THE SWEAT TEST IN THE DIAGNOSIS OF FIBROCYSTIC DISEASE OF THE PANCREAS

BY

ETHEL FINCH

From the Department of Pathology, Children's Hospital, Sheffield

(RECEIVED FOR PUBLICATION SEPTEMBER 3, 1956)

J. clin. Path. (1957), 10, 270.

The sweat test for the diagnosis of fibrocystic disease of the pancreas owes its origin to an observation made during the heat wave of 1948 in New York (Kessler and Andersen, 1951) that more than half of the children admitted to hospital with signs of heat prostration were cases of fibrocystic disease of the pancreas. Although the serum sodium and chloride concentrations were much reduced the children had no history of prolonged vomiting, intestinal loss, kidney or adrenal dysfunction. It was postulated that there was some derangement of the sweating mechanism and that excessive electrolyte loss may have occurred through the skin.

In 1953 a preliminary report was published of the sodium and chloride concentrations in the sweat from eight patients with fibrocystic disease of the pancreas together with those from a similar number of control patients of the same age group (Darling, di Sant'Agnese, Perera, and Andersen). This showed that the former group excreted four to five times as much sodium and chloride in the sweat as did the controls. Di Sant'Agnese, Darling, Perera, and Shea (1953) later published a much larger series of results which have confirmed the earlier findings of the persistently high concentration of sodium and chloride in the sweat of patients with fibrocystic disease of the pancreas.

The purpose of this communication is to report a similar series of investigations done in Sheffield Children's Hospital. An attempt is also made to compare the value of the sweat test with that of other laboratory tests usually performed on patients with steatorrhoea, failure to thrive, and chronic respiratory lesions.

Methods

The Sweat Test.—A modification by Shwachman, Higgins, and Dooley (1954) of Darling's (1948) method was used.

Sweat is collected by applying a pad of gauze about 3 in. square (washed in distilled water and dried) to the lower part of the patient's back, which has previously been washed with distilled water and dried. The gauze is covered with a piece of waterproof plastic material held in place with adhesive tape. It is important that the gauze should be handled with rubber gloves to prevent contamination from the skin of the person performing the test.

The body of the patient is enveloped in a plastic bag (the type used for storing clothes and obtainable in a variety of sizes) which is secured on the shoulders by tying with tape or bandage.

After wrapping well in a blanket, the child is put in a cot in a cubicle maintained at 80°-85° F. After one and a half to two hours, during which time the child should sweat freely, the sweat-soaked gauze is transferred to a stoppered flask which has previously been weighed with the dry gauze. The flask and gauze are reweighed and thus the amount of sweat is found.

A known volume of distilled water (usually between 20 and 40 ml. is sufficient) is added, and the sweat leached out. Sodium is estimated by means of the flame photometer and chlorides by any suitable method.

The results are expressed in m.Eq./litre.

A minimum of 0.5 g. sweat is required.

The Lipiodol Test (Silverman and Shirkey, 1955).—Dietary restriction is not necessary, but pancreatic enzyme therapy must be stopped for at least 48 hours before the test. A sample of urine is obtained before giving the patient lipiodol.

Dose of Lipiodol.—For patients weighing 10-20 kg. the dose is 0.5 ml./kg. Not less than 5 ml. and not more than 10 ml. should be given.

Samples of urine to be tested for iodine are obtained at 12, 18, and 24 hours after the administration of lipiodol. However, if there is difficulty in collection, one specimen of urine taken between 12 and 18 hours is sufficient.

Urine samples are diluted 1:1, 1:2 up to 1:16. After acidification with 8N nitric acid, the samples are tested for iodine with freshly prepared 1% starch. A blue colour persisting for five minutes is regarded as positive.

Normally, iodine is present in at least four of the dilutions and usually in all six. Urines from patients with fibrocystic disease of the pancreas show either no iodine or a trace in the first and second tubes.
It has been found that debilitated children who have an acute or chronic illness can give negative results, but after recovery from their illness they show normal function. This test therefore only excludes fibrocystic disease.

Faecal and Duodenal Trypsin.—The gelatine tube method was used (Emery, 1952).

Fat Balance Tests.—Three- or five-day collections of food and faeces were examined for fat content. Fat was estimated by Cammidge’s (1914) method.

Material

During the year March, 1955, to March, 1956, nine patients between the ages of 2 weeks and 7 years with fibrocystic disease of the pancreas were available for study. In five, the diagnosis was made on the clinical assessment supported by the laboratory findings of absent or low duodenal trypsin, and the presence of large amounts of neutral fat in the stools with low fat absorption. In the other four cases the diagnosis was made on clinical grounds supported by the lipiodol test, and also the trypsin activity of the faeces.

Control patients included those with steatorrhoea, failure to thrive, and chronic respiratory lesions. The diagnosis of fibrocystic disease of the pancreas was ruled out in these patients either by the presence of faecal and duodenal trypsin in normal amounts or by a lipiodol test and/or normal fat absorption.

Results

Table I shows the range of concentration of sodium and chloride in 12 samples of sweat from nine patients with fibrocystic disease together with 40 samples from control patients. Fig. 1 gives the distribution of these figures.

Table I

</table>

The highest sodium concentration of the sweat in control patients is 76 m.Eq./litre, with an average concentration of 28·3 m.Eq./litre, whilst the lowest sodium concentration in the sweat from patients with fibrocystic disease of the pancreas is 86 m.Eq./litre, with a mean level of 108 m.Eq./litre.

Similarly, the highest chloride concentration of the sweat in the control series is 39 m.Eq./litre and the mean value 15·4 m.Eq./litre, whilst the lowest chloride concentration of the sweat in patients with fibrocystic disease of the pancreas is 85 m.Eq./litre, with a mean value of 110 m.Eq./litre.

Table II gives the result of fat balance tests, faecal and duodenal trypsin activity, lipiodol tests, and concentration of sodium and chloride in sweat from 10 control patients.
Table III gives the results of fat balance tests, faecal and duodenal trypsin activity, lipiodol tests, and concentration of sodium and chloride in the sweat from 10 patients with steatorrhoea, i.e., five patients with coeliac disease and five with fibrocystic disease of the pancreas.

The fat balance tests on the patients with steatorrhoea show the typical high fat output with low percentage absorption compared with the control group. Faecal and duodenal trypsin activity in patients with coeliac disease is comparable with that of the control patients, while the children with fibrocystic disease of the pancreas show, on the whole, less trypsin activity. Similarly, the lipiodol tests performed on patients with coeliac disease show the same degree of lipase activity as do the control series, whereas those on patients with fibrocystic disease of the pancreas show none or only slight lipase activity.

The sodium and chloride concentrations of the sweat of the control patients and those with steatorrhoea fall in the same range, whereas those from the patients with fibrocystic disease are four to five times as high as these other two groups.

Discussion

All of the nine cases of fibrocystic disease that we examined showed a persistently high level of sodium and chloride content. These levels were beyond any found in the normal series. The findings confirm completely those made by di Sant'Agnese et al.

We found no relationship between the degrees of pancreatic and pulmonary involvement and the levels of sweat electrolytes. The same high levels were shown in the sweat from two cases of meconium ileus at 6 and 8 weeks of age respectively, as in the older well-developed cases. This again confirms the findings of the American workers (di Sant'Agnese et al., 1953).

The possible cause of this electrolyte abnormality of sweat in the fibrocystic syndrome has been discussed at length by di Sant'Agnese (1955). This abnormality would appear to be an inherited factor, for some parents of affected children show similar high sweat sodium and chloride concentrations, but it is not known if these parents have been affected in this way throughout the whole of their lives (Schwachman, 1955).

Our findings suggest that the occurrence of high sweat electrolyte concentrations together with relevant clinical features is diagnostic for fibrocystic disease of the pancreas.

Patients with adrenal insufficiency may have high sweat electrolytes, but these revert to normal or subnormal levels on treatment with D.O.C.A. or A.C.T.H. (Conn, 1949). Neither of these drugs has any significant effect on the sweat electrolytes in fibrocystic disease (di Sant'Agnese, 1955).

The value of this test is twofold: it appears to give the same results at all stages of the disease and can be carried out whilst the patient is on pancreatic therapy.

Conclusions

(1) From the data already acquired it appears that sweat sodium above 80 m.Eq./litre, and chlorides above 60 m.Eq./litre, together with relevant clinical data, are diagnostic of fibrocystic disease of the pancreas.

(2) It is the only test which gives similar results at any stage of the disease.

(3) It is the only test in which results are not invalidated if the patient is receiving pancreatic therapy.

I would like to thank the nursing staff of the hospital for the collection of sweat from the patients, and Drs. J. L. Emery and J. C. Haworth for their help and criticism in the writing of this paper.
