Coagulation studies in massive pulmonary haemorrhage of the newborn

J. T. ROBERTS, A. J. DAVIES, AND A. L. BLOOM

From the Welsh National School of Medicine, Institute of Pathology, Royal Infirmary, Cardiff

SYNOPSIS Coagulation studies were performed on two newborn infants with fatal massive pulmonary haemorrhage. The first showed a reduced level of plasma fibrinogen with defective thrombin-fibrinogen reaction, corrected by protamine, and defective thromboplastin generation. In the second case, a premature infant, the fibrinogen level was normal but there was a severe defect in thromboplastin generation with evidence of an inhibitor. A relationship between the pulmonary haemorrhage and coagulation defects is suggested but not established.

The occurrence of massive pulmonary haemorrhage in the newborn is well recognized. In a classical case a child, who may previously have been well, rapidly becomes sick when about 3 days old, bleeds from the mouth and nose, and dies in a matter of hours. At necropsy the respiratory passages are filled with blood, the appearance suggesting 'that the infant drowns in its own blood' (Potter, 1961).

Ahvenainen and Call (1952) did not think that pulmonary haemorrhage was a separate distinct entity, and they noticed kernicterus, infection, over-transfusion, congenital heart disease, intracranial haemorrhage, and a prolonged prothrombin time as associated features. Claireaux (1958) and MacGregor (1960) both subscribe to the existence of massive pulmonary haemorrhage of obscure aetiology. Claireaux thought that in the mature child anoxic damage to the pulmonary capillaries might be responsible, and that infection was an unlikely cause. Often there is no bleeding at other sites.

Pulmonary haemorrhage of varying degree is a common finding at necropsy in neonates. Vejlsen (1944) found a 10% incidence and Thorburn (1963) in Jamaica one of 8%. Thorburn thought that inhalation of gastric contents might be responsible. In Singapore, Sivanesan (1961) found an incidence of 13% and that it occurred both with and without cerebral haemorrhage. Mann and Elliott (1957) found pulmonary haemorrhage in children dying of cold. Finally Butler and Bonham (1963) found an increased mortality from massive pulmonary haemorrhage in dysmature children, that is children who are below the expected weight for their gestational age.

In this paper we report coagulation studies on two cases. Both showed massive pulmonary haemorrhage. The first was a post-mature child who presented with sudden illness. The blood showed hypofibrinogenaemia with abnormalities of the thrombin-fibrinogen reaction. The second was a premature child, ill from birth, with hypoglycaemia and hypothermia, and finally massive bleeding. Cerebral haemorrhage was also present. The blood in this case showed a circulating inhibitor of thromboplastin generation.

CLINICAL FEATURES AND NECROPSY FINDINGS

CASE 1 This child was born to a 39-year-old gravida two, blood group A Rh positive, with negative Wassermann reaction. At the age of 17 she had an ovarian cystectomy and at the age of 34 she had a 21-month course of chemotherapy for pulmonary tuberculosis. At the same age she had a miscarriage when three months pregnant. Since that time she has suffered from chronic bronchitis. In her second pregnancy because of unstable lie, together with obesity and mild hypertension (130/85 mm. Hg), elective lower segment Caesarean section was performed when she was 18 days post-mature by dates. Operation was uneventful. She was given anticoagulants in the puerperium for varicose leg veins. The placenta weighed 700 g. and was recorded as being gritty with infarcts on both surfaces.

The child breathed within 30 seconds and gave no initial cause for alarm. Routine pharyngeal suction was performed but neither oxygen nor vitamin K were given. Bottle feeds were taken well. Birth weight was 3,755 g. and blood group A Rh positive. The Coombs test was negative.

When 3 days 15½ hours old he was found in his cot at 5.30 a.m. having convulsions. Temperature was 42°C. and the skin was mottled. He started to bleed from the mouth and nose, but no rash or petechiae were present.
Coagulation studies in massive pulmonary haemorrhage of the newborn

He received hydrocortisone 100 mg. i.v. (repeated 8.30 a.m.), ampicillin 62.5 mg., cloxacillin 62.5 mg. i.v., chloramphenicol 50 mg., and phenobarbitone grain ¼. A drip was set up and 39 ml. of fresh frozen plasma given over a period of three hours, but he continued to bleed. His temperature had fallen to 36°C. by 8.0 a.m. Blood was taken at 9.30 a.m. from the left femoral artery (specimen A). At 10.45 a.m. the child died and blood was immediately taken by cardiac puncture (specimen B).

A necropsy was performed one and a quarter hours after death. The body was that of a pale mature child. Crown-heel measurement was 49 cm., crown-rump 34 cm. There were bruises at the neck and groins at the sites of needle puncture. Blood was present around the mouth and nose. Internally the respiratory passages were almost entirely filled with blood except for the anterior fringe of the lungs (Fig. 1). The left lung (all organs as fixed weights) weighed 44 g., the right 58 g. There were no pleural effusions. Other organs were pale in contrast. There was a little bruising in the oesophagus, behind the larynx. The liver weighed 124 g. The brain weighed 380 g. and was pale with no haemorrhage. The stomach was distended with air and showed a number of shallow erosions. Other organs were unremarkable.

On microscopy massive intrapulmonary haemorrhage was confirmed. The gastric erosions showed no surrounding reaction.

**CASE 2** This child was born to a 23-year-old primigravida, blood group O Rh positive with negative Wassermann reaction. At the age of 20 she had an ovarian cystectomy. In the first few weeks of this pregnancy she suffered from hyperemesis. At 30 weeks' gestation she was admitted with premature rupture of the membranes. Forty-eight hours after the rupture spontaneous delivery took place, aided by an episiotomy. Labour lasted 10½ hours. The placenta (425 g.) was recorded as small but healthy.

The child breathed in 30 seconds. Half an hour after birth his temperature was 35°C. and he showed early signs of respiratory distress. He was treated with oxygen, vitamin K, 1-5 mg., and antibiotics. Over the 63½ hours of his life he was never well. Treatment was continued with a regime of intravenous sodium bicarbonate and dextrose. Vitamin K, 1-5 mg., was repeated on the first day. His true blood glucose level was 26 mg. % on that day and 51 mg. % on the second, temperature 34°C., blood pH 7-3. On the third day 7 ml. of fresh frozen plasma was given. After this, five hours before death, a sample of blood was taken from a scalp vein for coagulation studies. A little later fresh blood poured from the larynx. His blood pH was 6-0, pCO₂ 150. He was intubated and put on intermittent positive pressure respiration but died.

A necropsy (Dr. K. M. Laurance) was performed 24 hours after death. The body was that of a premature male infant, pale and slightly icteric, with petechiae on the trunk. Weight was 1,630 g., crown-heel measurement 42 cm., crown-rump 27 cm. Internally the respiratory passages were extensively filled with blood. The left lung

![FIG. 1](image-url) **Cut surface of right lung and pleural surface of left lower lobe of case 1 to show the extent of haemorrhage. The pale fringe at the lower edge of the left lower lobe is the only normal lung.**

![FIG. 2](image-url) **Photomicrograph of the lung of case 2 to show membranes in the bronchi stained black for fibrin. Respiratory epithelium also appears dark but the haemorrhage is not well shown by this technique. Mallory's P.T.A.H. × 80.**
(fixed weights) was 20 g., the right 25 g. The heart and thymus showed a few petechiae. The liver weighed 53-5 g.; the brain, 150 g., showed bilateral intraventricular haemorrhages. There was a mild serosanguineous subdural effusion. Other organs were unremarkable.

Microscopy confirmed the massive pulmonary haemorrhage. The lungs showed extensive atelectasis and hyaline membranes were present. Some of these membranes, situated particularly in the bronchi, were positive with Mallory's phosphotungstic acid haematoxylin stain (Pearse, 1960) for fibrin (Fig. 2).

LABORATORY METHODS

Blood was collected into 3-8% w/v tri-sodium citrate in the proportion of 1 part of citrate to 9 parts of blood. Plasma was separated by centrifuging at 3,000 r.p.m. for 10 minutes and stored at —20°C. Tests were performed within 24 hours except where stated.

STANDARD COAGULATION TESTS One- and two-stage prothrombin times were performed as described by Biggs and Macfarlane (1962). The thromboplastin generation tests were performed on unadsorbed plasma as described by Hicks and Pitney (1957).

THROMBIN CLOTTING TIMES To 0-1 ml. of plasma was added 0-1 ml. of 0-85% saline and the clotting time at 37°C determined on the addition of 0-1 ml. of a solution of bovine thrombin (Parke Davis). The thrombin was diluted with saline so that the clotting time of normal adult plasma under the same conditions was approximately 15 seconds.

Calcium thrombin clotting times were performed as above except that the thrombin was diluted in M/40 calcium chloride.

In some experiments protamine sulphate, 100 mg. per 100 ml., was substituted for the saline in the thrombin clotting time.

PLASMA FIBRINOGEN This was measured as described by Varley (1960) modified as follows. Plasma, 0-2 ml., was added to 0-5 ml. of normal saline and clotted at 37°C with 0-1 ml. of bovine thrombin, 25 units per ml. The fibrin was subsequently harvested and estimated as tyrosine as described by Varley (1960). In some experiments 0-1 ml. of protamine sulphate 100 mg. per 100 ml. was included with the plasma. This addition did not affect the fibrinogen value of three samples of normal adult plasma.

RESULTS

CASE 1 Two samples of blood were tested. Sample A was taken 75 minutes before death and sample B was taken by cardiac puncture immediately after death.

Thrombin clotting time tests The results of these are shown in Table I. The thrombin clotting times of both samples were grossly prolonged unless protamine was added when fine clots were formed in 16 seconds. Calcium shortened the prolonged thrombin clotting time of sample B but this was still very abnormal. Thrombin clotting times (without calcium) were also performed on mixtures of sample B with normal plasma in varying proportions. The results are shown in Table II. A weak inhibitory effect on the thrombin-fibrinogen reaction of adult plasma is shown.

1Sample A was taken before death. 2Sample B was taken at death.

Plasma fibrinogen Initial attempts to assay plasma fibrinogen with thrombin alone were unsatisfactory because the plasma would not readily clot. Highest values were obtained when 0-1 ml. of protamine sulphate was added to the assay mixture on samples stored for seven weeks at —20°C. Then 128 mg. of fibrinogen per 100 ml. was detected in sample A and 78 mg. in sample B.

Thromboplastin generation test Thromboplastin generation in both samples was grossly defective (Table III). Mixtures of patient’s plasma with various proportions of normal plasma were made and thromboplastin generation tests performed on each mixture. The results, also shown in Table III, indicate that a potent inhibitor of thromboplastin generation was present in sample B but this was not so obvious in sample A. Insufficient of the latter sample was available to justify further attempts to detect inhibition.

In summary the coagulation defect in this patient’s plasma consisted of a reduced level of fibrinogen, prolonged thrombin clotting time corrected by protamine, and defective thromboplastin generation.

CASE 2  The blood from this infant was collected five hours before death and only a very small amount of plasma was available for study.

*Standard coagulation tests*  The results of thrombin clotting times, one-stage prothrombin times, and two-stage prothrombin assays are shown in Table IV.

The thrombin clotting times both with and without calcium were slightly prolonged as compared to normal adult plasma, but were within the normal range for neonates (Roberts, Gray, and Bloom, 1966). There was moderate prolongation of the one-stage prothrombin time and mild deficiency of prothrombin. The clotting times in these tests were of normal appearance and the plasma fibrinogen level was 213 mg./100 ml.

*Thromboplastin generation test*  Thromboplastin generation was grossly abnormal (Table V) and the patient’s plasma failed to correct the defect present in both severe factor VIII-deficient (haemophilic) and factor IX-deficient (Christmas disease) plasma. The results of mixing experiments with normal plasma are also shown in the table and suggest the presence of an inhibitor of thromboplastin formation. Thus two parts in 10 of normal plasma failed to correct the patient’s plasma, and two parts of patient’s plasma slightly impaired thromboplastin generation in normal plasma.

In summary the coagulation defect in this patient’s plasma consisted of a moderate prolongation of the one-stage prothrombin time and reduction of thrombin, but a severe defect of thromboplastin generation was associated with the presence of an inhibitor.

**DISCUSSION**

Surveys of fibrinogen values in the newborn show that they are a little lower than in the adult (Taylor, 1957). However, de Souza, Ferreira, Gomes, and Estrela (1953), using a calcium clotting method, found four values of 50 mg. per 100 ml. in 50 newborn infants, none of whom showed abnormal bleeding. Hartmann, Howell, and Diamond (1955) refer briefly to two cases. In one there was sepsis with severe liver damage and multiple coagulation defects, including a low fibrinogen value, but in the other hypofibrinogenenaemia was associated with active fibrinolysis. Valentine (1958) described a child of a mother who had antepartum haemorrhage, hypofibrinogenenaemia, and accelerated fibrinolysis. The child’s initial fibrinogen level (as measured by a thrombin clotting time method) was 7.5 mg./100 ml. and fibrinolysis was increased. The child survived but with evidence of cerebral damage. Reerink-Brongers and De Koningh (1964) also found a low plasma fibrinogen level, 55 mg./100 ml., in a child with suspected cerebral haemorrhage.

Assay values of clottable fibrinogen can sometimes be increased by adding protamine to the plasma. Such was the situation in case 1 of the present study. While the distinction by this means between true and apparent hypofibrinogenenaemia may reflect some difference in pathogenesis, the amount of fibrinogen capable of clotting normally in unmodified plasma is likely to be the important factor in maintaining haemostasis.

A prolonged thrombin clotting time may be caused by lack of fibrinogen. The fact that protamine caused considerable reduction of this time, however, suggests that in our case another factor is involved. Prolongation of the thrombin-fibrinogen reaction usually develops during active fibrinolysis and fibrinogenolysis (Fletcher, Alkjaersig, and Sherry, 1962). A similar phenomenon previously reported by Niewiarowski and Kowalski (1958) was reversed by protamine. An inhibitor of thromboplastin generation may also develop during fibrinogenolysis (Niewiarowski, Latallo, and Stachurska, 1959). Studies of the fibrinolytic system were not performed in our cases but the presence of abnormalities, particularly in case 1, which could result from activation of this system, suggests that this may be concerned in the pathogenesis of the coagulation defects observed. Possibly fibrinogen breakdown products inhibit the generation of thromboplastin and prevent normal fibrin polymerization.
Prolongation of the thrombin clotting time reversible by protamine sometimes accompanies the obstetric defibrination syndrome (Bloom and Campbell, 1965). The change seen in case 1 may therefore represent the defibrination syndrome of the newborn. Boyd (1965) has postulated a similar condition in the newborn on the basis of fibrin thromboembolism which he describes in the vessels as seen in histological section from necropsy material. One of us has observed similar deposits in a newborn child dying with severe haemorrhage. In the present study we found no such evidence of intravascular coagulation but these deposits may be labile and easily lysed.

The coagulation defects in case 2 do not particularly suggest hyperactive fibrinolysis. Although an inhibitor of thromboplastin generation may develop in this state there was no other supportive evidence and the fibrinogen level was normal. The prematurity of the infant may have contributed to some of the coagulation factor deficiencies but the cause of the inhibitor is not known.

No causal relationship between the presence of massive pulmonary haemorrhage and the severe coagulation defects described has been shown in the present study. However Cain and Crane (1965) also described a child with massive pulmonary haemorrhage whose blood would not clot on the addition of thrombin. Severe umbilical bleeding had preceded the test and there was evidence for increased fibrinolysis. Our observation of a grossly prolonged thrombin clotting time in the blood of apparently normal newborn infants (Roberts et al., 1966) suggests that these changes may not merely be terminal events in severely ill children. It is also unlikely that the infusions of fresh frozen plasma given to our patients contributed to the defect. These have never been seen in patients similarly treated for other disorders. Further studies correlating the coagulation and fibrinolytic systems in normal and affected newborn infants may show if bleeding is related to such defects as those we describe.

We would like to acknowledge the generous help given by Dr. O. P. Gray, who made the clinical diagnosis in these two cases, also the cooperation of Dr. K. M. Laurance. Professor Jethro Gough kindly gave advice.
