Gastrointestinal lymphoma in childhood

C. L. BERRY AND JEAN W. KEELING
From the Department of Morbid Anatomy, Institute of Child Health and Hospital for Sick Children, Great Ormond Street, London

SYNOPSIS Thirteen cases of lymphoma of the bowel in infancy and childhood are presented. There is a marked preponderance in males. The tumour most commonly presents with abdominal pain and intestinal obstruction; the prognosis is poor. Histological findings characteristic of the 'Burkitt' type of lymphosarcoma do not apparently influence survival.

Primary neoplasms of the gastrointestinal tract are infrequent in childhood and comprise less than 1% of tumours seen in this age group. The majority of the recorded cases are tumours of the reticuloendothelial system. Several centres have published small series describing intra-abdominal lymphosarcomata alone or as part of a review of malignant lymphomat in childhood (Bailey, Burgert, and Dahlin, 1961; Jones and Klingberg, 1963; Rosenberg, Diamond, Dargen, and Craver, 1958; Sullivan, 1962; Cutler, Stark, and Scott, 1945; Charache, 1956; Maxwell, 1954; Mestel, 1959).

We present here a review of 13 primary malignant gastrointestinal lymphosarcomata, with an assessment of their course, response to therapy, and histological appearance.

Materials and Methods

During the 10-year period 1960-69, 15 primary tumours of the gastrointestinal tract have been seen in this hospital (upper age limit is approximately 13 years). Two were teratomata arising in the gastric wall and have been reported elsewhere (Atwell, Claireaux, and Nixon, 1967; Berry, Keeling, and Hilton, 1969). From the remaining 13 cases, sections of the surgical specimens were stained with haematoxylin and eosin, haematoxylin-van Gieson, Gordon and Sweet's reticulin stain, and the Unna-Pappenheim techniques. Necropsy material was available from one case (case 2).

Results

The clinical details, age at presentation, sex, duration of symptoms, operative findings, subsequent treatment, and progress are shown in Table I.

PATHOLOGICAL FINDINGS

Typical macroscopic appearances are seen in Figs. 1 and 2 (case 5) and Figs. 3 and 4 (case 7).

Microscopic findings are summarized in Table II. Ten tumours are lymphoblastic lymphosarcomata and are composed of closely packed round cells having prominent nuclei with little cytoplasm (Fig. 5). Five of these tumours contain large phagocytic reticular cells giving a 'starry sky' appearance and in three instances other cytological characteristics of the 'Burkitt' type of lymphoma (ill-defined cytoplasmic border, small cytoplasmic vacuoles, prominent nucleoli, frequent mitoses, occasional pyroninophilia) are present (Fig. 6). Involvement of the muscle coats of the bowel wall leads to the appearance of altered muscle cells within the tumour in some instances.

Three tumours are considered to be reticulum

¹Burkitt-like morphology

cell sarcomas, and are composed of pleomorphic reticulin cells; binucleate cells are seen. Reticulin fibres are seen between cells and thicker condensations of reticulin divide cell masses.

Bone marrow examination was normal in cases 3, 4, 9, 11, 12, and 13. The narrow aspirate in case 1 showed granulocytic hyperplasia but no tumour infiltration. Appearances were within normal limits in case 2 initially but terminal aplasia was found. In case 6 the tumour cells were found terminally. Bone marrow examination was not performed in cases 5, 7, 8, and 10.

Necropsy was performed on case 2; he died two years and nine months after resection of an ileocaecal tumour. Bone marrow aplasia and pulmonary fibrosis had developed and was apparently associated with cytotoxic drug therapy.

There was cultural and histological evidence of disseminated moniliasis with involvement of the central nervous system. Residual tumour was not found.

Tumour had involved bone marrow terminally in case 6, with the appearance of tumour cells in the blood. Metastases occurred in cases 1, 3, 4, 8, 10, and 12. Transcoelomic spread of tumour to other abdominal viscera was probable in case 13.

Discussion

The age range at presentation was from 1 year 11 months to 12 years 10 months in our series.

Twelve of the 13 patients were male; a similar degree of male preponderance was noted in the series described by Mestel (1959), 11 male and two female cases, but was less marked in other studies. Bailey et al (1961) found a male-to-female ratio of 3.4:1, and Jones and Klingberg (1963) had a male-to-female ratio of 2.6:1.

The 13 tumours constitute 0.6% of all tumours
seen at this hospital since 1957 (excluding leukaemia) and 37% of the lymphomata.

The presence of Burkitt-like morphology was not associated with a better prognosis and the phagocytic activity of histiocytes included in the tumour does not appear to be evidence of an effective host response to the tumour.

Two of the cases were brothers (cases 2 and 6): the familial tendency to develop lymphomata has been discussed elsewhere (Rigby, Rosenlof, Pratt, and Lemon, 1966) and will not be considered further here.

Abdominal pain and distension were the most frequent presenting symptoms, as in most series of both adult and childhood age groups (see Mestel, 1959, for bibliography).

Investigation showed no distinctive features, and in general findings were those of intestinal obstruction and intussusception.

Primary treatment was surgical and was designed to achieve complete resection (cases 2, 3, 4, 5, 6, 7, 9, 11, and 12) or palliation (cases 1 and 13). In cases 8 and 10 biopsy only was performed and no further treatment was given. Cases 3, 4, 5, and 13 were treated by radiotherapy and cases 1, 2, 9, 11, and 12 by cytotoxic drugs in addition. Four patients are alive but two have been diagnosed only in the last few months. Of the remaining two, case 1 is alive with evidence of extensive disease after six months. There is one long-term survivor (case 7) who is free of disease six years after radical surgery alone. These dismal results compare with those found in other series (Charache, 1956; Mestel, 1959). Bailey et al (1961) have achieved some success with surgery and radiotherapy in a small series (three long-term survivors from nine cases).

These cases presented over a period of 10 years, and policy regarding chemotherapy and radiotherapy probably reflects common usage at that time, except in cases 8 and 10 where extensive metastatic spread was present at laparotomy and specific antitumour therapy was withheld. Bone marrow examination was not performed in all cases, and the use of antitumour therapy was not based on the findings in the blood.

In general this is a tumour with an exceedingly grave prognosis. Its relative infrequency and the varied methods of treatment employed prevent a rational assessment of the efficiency of various therapeutic regimes but it seems likely that radical surgery with radiotherapy aimed at preventing local recurrence is a rational mode of treatment in view of the present state of knowledge of this disease.

C. L. Berry is the Gilson scholar of the Worshipful Society of Apothecaries of London.

We should like to thank the Photographic Department of the Hospital for Sick Children for Figures 1-4.
