Renal dysplasia

R. A. RISDON

From the Department of Morbid Anatomy, The Hospital for Sick Children, Great Ormond Street, London

Part I  A clinico-pathological study of 76 cases

SYNOPSIS  The clinical and pathological findings in 150 children submitted to partial or total nephrectomy have been reviewed. Histological examination of the kidney removed at operation showed evidence of renal dysplasia in 76 (51%). These 76 patients were divided into three main groups on the basis of the pathological changes found in the kidney and the associated urinary tract anomalies. In group 1, gross cystic renal dysplasia was associated with absence or atresia of the renal pelvis and ureter. In group 2, renal dysplasia was segmental; the ureter, although patent, had some anatomical or functional abnormality which resulted in urinary stasis or reflux. In many of these patients dysplasia was confined to the upper pole of a ‘duplex’ kidney which was drained by an ectopic ureterocele. In group 3, renal dysplasia was associated with obstruction of the lower urinary tract, most commonly by posterior urethral valves. In group 1 dysplasia was total, involving the whole kidney, whilst in groups 2 and 3 dysplasia tended to be segmental; in the majority some normal renal tissue was present. Pyelonephritis was a very common complication, but was present only in patients from groups 2 and 3, in whom a lumen was present in the draining ureter, and not in patients from group 1 in whom the ureter was atretic or absent, and the kidney not functioning. It appears that urinary obstruction, stasis, or reflux are the principal factors predisposing to and promoting pyelonephritis in dysplastic kidneys. There seems to be no reason to suppose that dysplastic renal tissue is abnormally susceptible to infection since pyelonephritic changes were lacking in those cases in which dysplasia was most severe.

Renal dysplasia is the abnormal, disorganized development of renal parenchyma due to anomalous differentiation of metanephric tissue. Histologically the normal renal architecture is distorted; the glomeruli, tubules, and collecting ducts are deficient in number, appear morphologically immature, and often undergo cystic changes (Kissane, 1966). The extent of the abnormality varies from a grossly disorganized multicystic dysplasia involving the whole kidney to a less severe segmental change in which part of the kidney is unaffected. Osathanondh and Potter (1964), in a study of the pathogenesis of polycystic kidneys based on microdissection, concluded that cystic dysplasia was due to diminished branching of the ampullary portion of collecting ducts derived from the ureteric bud, with resulting cyst formation and failure to induce normal nephron formation in the metanephric blastema. The cause of inhibition of ampullary activity in these cases is unknown, but it has been suggested that the frequent association of urinary tract obstruction may be an important factor (Bernstein, 1968). The present study was undertaken in order to assess the frequency of renal dysplasia in kidneys surgically resected in children and to correlate the clinical and pathological changes found. Pyelonephritis complicating renal dysplasia was found to be confined to those cases in which the lumen of the draining ureter was patent.
Patients

The pathological material has been reviewed from 150 consecutive cases of children submitted to total or partial nephrectomy at the Hospital for Sick Children between 1962 and 1969. The case records of these children were also examined in order to correlate the clinical and histopathological findings. Seventy-three were boys and 77 girls, ranging in age between 1 week and 12 years 6 months at the time of operation. The kidney tissue removed was fixed in buffered formalin (pH 7-0) and between one and five blocks of tissue from each specimen were embedded in paraffin wax. Sections of 5 μ thickness were cut and stained routinely by Ehrlich’s haematoxylin and eosin (H & E) and, in the majority of cases, by van Gieson’s mixture. Other stains were also used when necessary.

The patients fell into six categories (Table I). The main clinical findings and pathological abnormalities, particularly the associated anomalies found in the ureters and lower urinary tracts, are shown. 'Hypoplastic' kidneys were congenitally small; the five examples examined all weighed less than 9 g. Gross multicystic kidneys were those in which the kidney consisted of a disorderly non-reniform mass of cysts of varying size, in which no normal renal parenchyma was recognizable. Partially cystic kidneys were those in which the structural disorganization and cystic change was somewhat less marked and in which some renal parenchyma was present.

Assessment of the Histological Changes

In each case the histological sections were examined for evidence of renal dysplasia and pyelonephritis.

Table I  Main clinical and pathological findings in 150 children submitted to partial or total nephrectomy

1The numbers in brackets refer to numbers of patients. 2Nine of these patients subsequently had the remaining lower pole removed.
Renal dysplasia: A clinico-pathological study of 76 cases

depended primarily upon disorganization of the renal parenchyma, and the presence of 'primitive' ducts. These structures are lined by columnar epithelium and surrounded by concentric mantles of cellular mesenchyme (Fig. 1). They are thought to be derived from the branches of the ureteric bud (Ericsson and Ivemark, 1958a). Often they are aggregated, forming nodular collections (Fig. 2). A case was classified as dysplastic only when these features were present. Foci of metaplastic cartilage (Fig. 3) were also regarded as definite evidence of renal dysplasia, but these were present in only a proportion of the cases showing parenchymal disorganization and 'primitive' ducts. Other so-called 'dysplastic' structures sought were 'foetal' glomeruli (Pasterнак, 1960), 'primitive' tubules and ductules (Ericsson and Ivemark, 1958a), and tubular and glomerular cysts (Rubenstein, Meyer, and Bernstein, 1961). These are illustrated in Figures 4 and 5.

Pyelonephritis

Histological evidence of pyelonephritis sought was the presence of conspicuous acute or chronic inflammation of the renal interstitial tissues and of the mucosa lining the renal pelvis (Figs. 6 and 7). Periglomerular fibrosis, glomerular sclerosis, and foci of tubular atrophy (Fig. 8) were almost invariably present in the inflamed areas.

Results

These are summarized in Tables II, III, and IV and in Figure 10.

Histological evidence of renal dysplasia was present in 76 (51%) of the 150 patients studied (Table II). These 76 patients were divided into three main groups (Table III) on the basis of the pathological changes found in the kidneys and the associated anomalies in the urinary tract.

Pyelonephritis was a common complication in the cases with renal dysplasia; histological

Fig. 6  Pyelonephritis. Marked interstitial chronic inflammation with lymphoid follicle formation. H. & E. × 40.

Fig. 7  Pyelonephritis. Chronic inflammation of the renal pelvis. H. & E. × 10.

Fig. 8  Pyelonephritis. Periglomerular fibrosis and glomerular sclerosis in an area of chronic inflammation. H. & E. × 40.
Evidence of this condition was present in 58 (76%), but was found only in patients in groups 2 and 3 (Table IV). Two patients in group 1 had clinical evidence of urinary tract infection (pyuria and bacteriuria) but in both the opposite kidney was abnormal; in one intravenous pyelography showed a small kidney with clubbed calyces, and in the other hydronephrosis due to stenosis of the pelvi-ureteric junction was found.

The blood urea concentration, which in each case was measured a few days before operation, was often raised in all three groups (Fig. 9). In group 1 the urea concentration was normal or moderately raised in all but two cases in which the levels were more markedly raised (141 and 153 mg/100 ml). In these instances there were marked abnormalities in the opposite kidney. In group 2, one case had a urea level of 150 mg/100 ml. This child died two days after operation. In the remainder the initial urea level was often raised, but in every case fell to less than 35 mg/100 ml following operation. In group 3 the blood urea was usually raised and was less than 40 mg/100 ml in only six cases.

Mortality was highest amongst patients in group 3, five of whom died of renal failure between three weeks and 30 months after operation. In group 1, one patient died of renal failure. This child had severe hydronephrosis of the contralateral kidney due to stenosis of the pelvi-ureteric junction. In group 2, one child died in the post-operative period. He had severe bilateral hydronephrosis due to an obstructing ectopic ureterocele in the urinary bladder.

**Discussion**

The criteria on which the histological identification of renal dysplasia is based are unsatisfactory. The diagnosis depends on the recognition of various 'dysplastic' structures in the kidney including 'primitive' ducts and tubules (Ericsson and Ivemark, 1958a), metaplastic cartilage

Renal dysplasia: A clinico-pathological study of 76 cases

Fig. 9 Blood urea estimations immediately before operation in the three groups of patients with renal dysplasia.

Fig. 10 Hydronephrosis. Flattening of the renal papilla and atrophy of the medulla. The collecting ducts are separated by fibrous connective tissue. H. & E. × 10.

(Bigler and Killingsworth, 1949), 'foetal' glomeruli (Pasternack, 1960), and renal cysts (Rubenstein et al, 1961). However, Bernstein (1968) has demonstrated in the kidneys of young children that an apparently 'primitive' morphology may be induced in glomeruli, tubules, and ductules as a result of ischaemic damage, or even by scarring following renal biopsy, without there being any suggestion of maldevelopment. For these reasons, in the present study, the histological diagnosis was based on the presence of structural disorganization of the renal parenchyma as a result of abnormal development, and on the presence of 'primitive' ducts of the type described by Ericsson and Ivemark. These structures are thought to represent branches of the ureteric bud, and are not seen in conditions other than renal dysplasia (Bernstein, 1968). Bars of metaplastic cartilage have also been regarded as definite evidence of renal dysplasia (Bigler and Killingsworth, 1949), but since they are not always present even in obviously dysplastic kidneys, their presence was regarded more as useful confirmation of the diagnosis. Dysplastic changes may sometimes be confused with those due to hydronephrosis, particularly when the two conditions coexist. Flattening of the renal papillae as a result of back pressure causes a tangential rather than a radial alignment of the collecting ducts. The ducts become separated by fibrous connective tissue which may condense around the tubules and mimic mantles of mesenchyme (Fig. 10). Such cases may account for descriptions of so-called pure medullary dysplasia (Gwinn and Landing, 1968). In the cases studied it was usually evident that hydronephrosis primarily produced atrophic changes in the medulla, the cortex becoming thin only at a late stage. In renal dysplasia the cortex was disorganized and usually markedly thinned by comparison with the adjacent medulla. 'Primitive' ducts were often aggregated together and formed nodules (Fig. 2), a feature not seen in pure hydronephrosis.

In the present series, histological evidence of renal dysplasia was found in 51% of cases. Consideration of the pathological changes in the kidneys and the associated urinary tract abnormalities allowed their division into three groups (Table III). In group 2 cases of 'duplex' kidney with double ureters were included with cases in which the kidneys were 'hypoplastic' or partially cystic. This was considered reasonable,
since in all the dysplastic changes were segmental, and in all the ureter draining the dysplastic kidney, whilst possessing a lumen, showed some structural or functional abnormality which resulted in urinary stasis or reflux.

Elevation of the blood urea concentration was seen in a proportion of patients from all three groups, but was most common in those in group 3 with obstruction of the lower urinary tract. In fact, in most cases in group 3 the initial blood urea level had been higher, but the establishment of bilateral ureterostomies or nephrostomies produced a fall in the blood urea. Nephrectomies were performed when urine formation was so slight as to suggest little useful renal function. In all cases in group 2 with raised blood urea concentrations, ectopic ureteroceles (Berdon, Baker, Becker, and Uson, 1968) were present in the urinary bladder. The fact that urea levels fell after operation suggests that the initial elevation may have been due to urinary obstruction by the uretercele. In group 1, the blood urea levels were markedly raised in two cases in which abnormalities were also present in the contralateral kidney and moderately raised (57 and 74 mg%) in two others. Both of these were young infants, less than 2 weeks old. The raised blood urea level in these cases may reflect a relative inability of the opposite 'normal' kidney to cope as a result of some functional immaturity.

The mortality was highest in patients in group 3, five of whom died of renal failure. This was not surprising since they all presented with bilateral hydronephrosis and hydrourereter and the resulting renal damage was sufficient to destroy entirely the function in at least one kidney.

Pyelonephritis was a very common complication in those patients with renal dysplasia. Histological evidence of pyelonephritis was found in 76% of the cases. This association has also been emphasized by others (Marshall, 1953; Ericsson and Ivemark, 1958b; Pasternack, 1960). These authors concluded that dysplastic renal tissue was abnormally susceptible to infection in much the same way as areas of scar tissue in the kidney (Rocha, Guze, Freedman, and Beeson, 1958). Marshall (1968) even suggested that most cases of pyelonephritis in the adult arise from infection of areas of renal dysplasia. In the present study, although pyelonephritis was common, it occurred only in patients in groups 2 and 3 in whom a lumen was present in the draining ureter, and not in group 1 in whom the ureter was absent or atretic, and the kidney was not functioning. Two patients in group 1 had clinical evidence of a urinary tract infection, but in both there were marked abnormalities of the opposite kidney. Such a finding is not uncommon in cases of cystic renal dysplasia (Pathak and Williams, 1964). In both these cases histological evidence of pyelonephritis was lacking in the resected dysplastic kidney. In any case, pyuria and bacteriuria in the voided urine could hardly have arisen in this kidney since it was effectively isolated by an atretic ureter.

It appears that a lumen is necessary in the draining ureter for infecting organisms to gain access to the dysplastic kidney. Structural or functional abnormalities in the ureter or lower urinary tract causing urinary stasis or reflux seem to be the most important factors in promoting pyelonephritis in dysplastic kidneys as in other situations. There is no reason to conclude that dysplastic renal tissue is abnormally prone to infection since pyelonephritis was absent in those cases in group 1 in which dysplasia was most widespread and severe. Absence or atresia of ureter in these cases may be a secondary phenomenon. Dysplasia was marked and affected the whole kidney and it seems unlikely that urine formation could have occurred at any stage in its development. It is possible that the maintenance of a lumen in the developing ureter requires the passage of urine and in its absence the lumen either does not develop or even the ureter may disappear.

References

Part II  A necropsy study of 41 cases

SYNOPSIS  The pathological findings at necropsy have been reviewed in 121 children with congenital malformations of the kidney and lower urinary tract. Histological examination of the kidneys revealed evidence of renal dysplasia in 41 (34%). Comparison of these 41 cases with other cases in which renal dysplasia was found in kidneys removed surgically showed a much higher incidence of bilateral involvement and of other associated major congenital abnormalities. Histological evidence of pyelonephritis was less common except in those cases in which renal dysplasia was associated with lower urinary tract obstruction. A total of 34 children with bilateral hydronephrosis and hydroureters due to congenital urethral obstruction was found, and in these cases severe degrees of renal dysplasia were present only in those dying in the first two months.

Many previous reviews have been made of multicystic and 'hypoplastic' renal dysplasia (Elkstrom, 1955; Spence, 1955; Coppridge and Ratliff, 1958; Parkkulainen, Hjelt, and Sirola, 1959; Vellios and Garrett, 1961) but rather less emphasis has been given to renal dysplasia associated with congenital lower urinary tract obstruction (Pathak and Williams, 1964; Rattner, Meyer, and Bernstein, 1963). For this reason a separate quantitative study was made of the incidence and degree of renal dysplasia present in the 34 children with obstruction of the lower urinary tract included in the present series.

Patients

A review of the necropsy records at the Hospital for Sick Children for the period between 1954 and 1969 revealed 157 congenital malformations of the kidney and lower urinary tract occurring in 121 children. Eighty-four were boys and 37 girls ranging between 1 day and 13 years 6 months at death. The various anomalies encountered are shown in Table I. In each case histological sections were cut of 5 μ and stained routinely by Ehrlich's haematoxylin and eosin (H and E); other stains were employed where necessary.

Assessment of the Histological Changes

In each case the histological sections were

examined for evidence of renal dysplasia and pyelonephritis using the criteria described previously (Risdon, 1970).

In addition a separate quantitative assessment of the degree of renal dysplasia present in the kidneys from the 34 children with bilateral hydronephrosis and hydroureters due to congenital lower urinary tract obstruction was made as follows: 0 = where there was no histological evidence of renal dysplasia. + = where occasional foci of renal dysplasia were seen, but most of the renal parenchyma was normally differentiated (Fig. 1). ++ = where renal dysplasia was segmental, with areas of normally and anomalously differentiated parenchyma present (Fig. 2). +++ = where renal dysplasia was total, but some separation of the renal parenchyma into cortex and medulla was discernible. Cystic changes tended to be prominent in the subcapsular zone (Fig. 3). ++++ = where dysplasia was total and complete disorganization of the renal parenchyma was associated with marked cystic changes (Fig. 4).

In 33 of the 34 cases sections from both kidneys were examined. In the remaining case, unilateral renal agenesis was present, and a section from the single kidney was examined.

Results

Histological evidence of renal dysplasia was present in 41 (34%) of the cases studied and was bilateral in just over half of them (23 cases).

The 41 children with renal dysplasia were divided into three groups (Table II) on the basis of the pathological changes in the kidney and the associated anomalies in the draining urinary tract as described previously (Risdon, 1970). Dysplasia was bilateral in 23 (63%) and additional congenital abnormalities were frequently present both in the urogenital system and also in other systems, particularly the cardiovascular and gastrointestinal systems. These are summarized in Table III.

Histological evidence of renal infection or pyelonephritis was present in two of nine cases from group 1, three of the 10 cases from group 2, and in 17 of the 22 cases from group 3.

Of the two cases affected in group 1, in the first, evidence of pyelonephritis was confined to the contralateral non-dysplastic kidney, in which there was hydronephrosis due to mid-ureteric obstruction. In the other case, there was focal abscess formation in the cystic dysplastic kidney and a pyonephrosis in the other kidney due to pelvi-ureteric stenosis. In group 2, the three cases

Children dying aged less than 2mths. Children dying aged 2mths or more.

**Fig. 5** Histological grading of the degree of renal dysplasia present in sections from each kidney in the 34 cases with congenital lower urinary tract obstruction correlated with the age at death.

With histological evidence of pyelonephritis were aged 6 weeks or more at the time of death, whereas the seven cases in which pyelonephritis changes were absent were aged 19 days or less at death.

Of the 34 cases with bilateral hydronephrosis and hydrourerets due to congenital lower urinary tract obstruction, histological evidence of renal dysplasia was present in 22 (65%). Severe degrees of renal dysplasia (+++, ++++) were present only in those children dying in the first two months (Fig. 5).

**Discussion**

In the previous account of renal dysplasia in surgically resected kidneys in children (part I) the cases were divided into three main groups according to the pathological changes in the kidney and the associated anomalies in the draining urinary tract. Group 1 comprised cases of gross multicystic renal dysplasia associated with absence or atresia of the ureter and renal pelvis (Fig. 6). In group 2 renal dysplasia was segmental, and the draining ureter, whilst it possessed a lumen, showed some structural or functional abnormality which interfered with urinary drainage (Figs. 7 and 8). In group 3, renal dysplasia was associated with bilateral hydronephrosis and hydrourater due to lower
Renal dysplasia: A necropsy study of 41 cases

Urinary tract obstruction (Fig. 9). A similar grouping was used to classify the cases in the present survey of postmortem cases, and this emphasized important differences in the relative incidence of cases placed in the various groups in the two series. In two cases of unilateral multicystic dysplasia discovered at necropsy, the draining ureter, although grossly narrowed and hypoplastic, was not entirely atretic. These cases were included in group 1 because the changes in the kidney were entirely similar to the other cases in the group in that the cystic changes were gross and no normal renal parenchyma was discernible. Four cases included in group 3 in the postmortem series had congenital absence of the abdominal muscles, and were examples of the so-called 'prune belly' syndrome (McGovern and Marshall, 1959). All four had bilateral hydronephrosis and hydroureters and severe renal dysplasia. In three there was urethral obstruction due to urethral atresia or stenosis, but in the fourth case, although the posterior urethra was dilated, no definite mechanical obstruction was demonstrated. Inclusion of this case in group 3 seemed justified, since in all other respects the findings were indistinguishable.

Amongst the surgical cases, the numerically largest category were those in group 2 with 'duplex' kidneys in which the upper pole was dysplastic. Only one such case was present in the necropsy series. In the whole survey of postmortem cases there were 11 instances of 'double kidneys' with pelvic duplication, but in none of these was there any parenchymal dysplasia. It is of interest that in all of these the double ureters fused to form a single structure before insertion into the bladder, and the ureteric orifice was normally situated in the trigone. In contrast, 'duplex' kidneys with dysplasia of the upper pole invariably had two separate ureters draining the upper and lower poles. In every case fully investigated the ureter draining the dysplastic pole was inserted ectopically into the bladder, and in the majority of cases this was associated with a ureterocele (Berdon, Baker, Becker, and Uson, 1968).

Cases of congenitally small 'hypoplastic' dysplastic kidneys, and partially cystic dysplastic kidneys placed in group 2, were slightly more common in the postmortem series. As in the surgical cases, structural abnormalities of the draining ureter were almost universal, being present in all but one case. The ureteric abnormalities were similar, and included ectopic insertion into the bladder, ureterocele, ureteric dilatation without obstruction, and ureteric hypoplasia.

In contrast to the surgical series in which all the cases placed in groups 1 and 2 had unilateral renal dysplasia, seven of the 19 postmortem cases in groups 1 and 2 showed bilateral involvement. In addition there were major congenital abnormalities in other systems in 10 instances. These anomalies, which are summarized in Table III, principally involved the cardiovascular and gastrointestinal systems, a finding also noted by Rubenstein, Meyer, and Bernstein (1961). These findings in groups 1 and 2 constituted the main difference between the surgical and necropsy series. Involvement of both kidneys or the presence of other major and often multiple congenital abnormalities were not compatible with survival.

In three of the cases placed in groups 1 and 2 in the necropsy series there was hydroureter of the contralateral kidney due to ureteric stenosis. In two the stenosis was at the pelviureteric junction and in the third the stenosis was at the junction of the upper and middle thirds of the ureter. Similar findings were present in two of the surgical cases. This type of abnormality in the opposite kidney is an important and not uncommon finding in cases of multicystic renal dysplasia, as has been emphasized by Pathak and Williams (1964). Early diagnosis of the contra-

lateral hydronephrosis is vital if progressive
destruction by back-pressure and ascending
infection is to be avoided in this single functional
kidney.

The pattern of secondary pyelonephritis
differed somewhat between the surgical and the
necropsy series. None of the surgically resected
dysplastic kidneys placed in group 1 showed
histological evidence of pyelonephritis. Of the
cases in group 1 found at necropsy, one case
showed evidence of infection in the dysplastic
kidney; scattered abscess formation and focal
pyogenic inflammation were present. However,
in this case infection was clearly blood-borne,
since a pyonephrosis due to pelvi-ureteric
obstruction was found in the opposite kidney.
This was the only instance of infection in a
multicystic dysplastic kidney in the 23 cases in
both series in which the draining ureter was
atretic or absent. This finding emphasizes the
importance of ascending infection in the patho-
genesis of pyelonephritis complicating renal
dysplasia (Risdon, 1970). Histological evidence
of pyelonephritis was less common in the cases in
group 2 in the present series, only three of the 10
cases being affected, whereas all but one of the 45
surgical cases in this group showed pyelo-
nephritic changes. This discrepancy probably
reflects the difference in ages in the two series.
The three cases in group 2 in the necropsy series
were all aged 6 weeks or more at the time of
death whereas the seven without pyelonephritic
changes were aged 19 days or less. These seven
cases all had either bilateral renal dysplasia or
other major congenital abnormalities, these
factors being responsible for their early death.

In all the cases found at necropsy to have
bilateral hydronephrosis and hydrouretters due
to congenital lower urinary tract obstruction,
including the cases of 'prune belly' syndrome,
death had resulted from renal failure. This was
variously due to a combination of pyelonephritis,
renal atrophy due to hydronephrosis, and renal
dysplasia. In order to assess the importance of
renal dysplasia in this context, quantitative
assessment was made in all cases of the degree of
renal dysplasia in sections from both kidneys.
Histological changes of renal dysplasia were
found in 22 (65%) of the 34 cases, and was
bilateral in 16. This compares with an incidence
of 10 out of 21 (eight bilateral) in a similar
from the six cases in which only one kidney
showed dysplastic changes, quantitative assess-
ment showed that the degree of renal dysplasia
present often varied in the two kidneys. In three
instances severe renal dysplasia was present in
one kidney and absent in the contralateral kidney.
The occurrence of such marked variation in the
degree of dysplasia in the two kidneys probably
explains the much higher incidence of renal
dysplasia in the surgical cases with congenital
lower urinary tract obstruction, all but one of
which were affected. In these, unilateral neph-
rectomy was performed to remove a non-function-
ing kidney. They were, therefore, highly selected
in terms of disparate function on the two sides,
and renal dysplasia might reasonably be expected
to be commoner in the resected organ. Corre-
lation of the age at death in the cases in this group
coming to necropsy with the degree of renal
dysplasia found in the kidneys showed that severe
degrees of dysplasia were associated with early
death, before the age of 2 months. Treatment of
ascending infection and relief of the obstruc-
tion should not be expected to affect the outcome
when both kidneys are severely deformed, but,
as Rattner and his colleagues have emphasized,
in other cases early diagnosis with surgical
intervention and treatment of infection may be
successful in preventing further progressive renal
damage.

I should like to thank Professor A. E. Claireaux
and Mr D. I. Williams for their helpful advice
and criticism in the preparation of this paper. I
am also indebted to Mr D. I. Williams for per-
mission to use the clinical records of the cases
studied.
