The distribution of plasminogen activator in the male genital tract

R. C. KESTER

From the Department of Surgery, Dundee Royal Infirmary

SYNOPSIS The distribution of fibrinolytic activity in the tissues of the male genital tract was studied by a histological technique. Preparations made from testis, epididymis, vas deferens, seminal vesicle, prostate, bulbo-urethral gland, and urethra showed that most activity was related to the blood vessels. However, inconsistent fibrinolytic activity related to epithelium was found in all parts of the genital tract. This epithelial activity was least in the testis, greater in the seminal vesicle and prostate gland, and was greatest in the bulbo-urethral gland and terminal urethra. No fibrinolytic activity could be demonstrated in relation to spermatozoa.

The cycle of coagulation and liquefaction of semen resembles the clotting and fibrinolysis of blood. Fibrinolytic activity appears in the blood when a pro-enzyme, plasminogen, is converted to the active protease, plasmin, by an 'activator'. This protease then digests fibrin. Similarly, when seminal fluid is ejaculated, it coagulates immediately and is then liquefied within about 20 minutes by proteolytic activity. Human semen contains a fibrinolytic substance which Huggins and Neal (1942) thought was a protease of prostatic origin, but it was later shown that the substance was in fact an activator of the plasminogen system (von Kaulla and Shettles, 1953).

Using the histological technique of 'fibrinolysis autography' (Todd, 1959), which reveals the topography of plasminogen activator in tissues, it has been shown that activator is concentrated not only in the vascular endothelium of the prostate, but also to a lesser degree in the epithelium of the glands and ducts (Kester, 1969). In the latter studies, the amount of activator demonstrable in the prostatic epithelium seemed insufficient to be the only source of the fibrinolytic activity of human seminal fluid. In an attempt to find the source of plasminogen activator in seminal fluid, the other tissues of the genital tract have now been examined by fibrinolysis autography.

Materials and Method

Tissues were taken from the reproductive organs of 14 adult males at routine necropsies within 24 hours of death (see Table I for clinical details). Blocks from the tissues of the male genital tract were embedded in paraffin wax, and sections of 6-7 microns were cut from the blocks and stained with haematoxylin and eosin. The sections were examined microscopically and those exhibiting a varying degree of lysis of the fibrinogen clot were photographed and prepared as autographs. The 'activator' was demonstrated by means of the 'fibrinolysis autography' technique of Todd (1959).

Case No. Age (yr) Cause of Death
1  68  Chronic lymphatic leukaemia
2  55  Cancer of caecum
3  46  Cerebral haemorrhage
4  58  Cancer of colon
5  82  Cardiac failure
6  77  Cancer of pancreas
7  44  Muscular dystrophy
8  60  Cerebral infarction
9  22  Multiple injuries
10 44  Myocardial infarction
11 63  Cancer of stomach
12 58  Cardiac failure
13 57  Myocardial infarction
14 61  Cancer of stomach

Table I Details of source of human tissue

Testis, epididymis, vas deferens, seminal vesicle, prostate, bulbo-urethral (Cowper's) gland, and urethra were each placed in a small polythene bag containing Veronal buffer saline (Biggs and McFarlane, 1962), pH 7-4, ionic strength 0-16, with sodium azide 0-1% as a bacteriostatic. The samples were 'quick frozen' by plunging the bags into a dry ice-acetone mixture and stored at \(-30^\circ C\) in the deep freeze. Tissue sections of about 8 microns thickness were cut from the blocks on a cryostat microtome before making the histological preparations.

PLASMINOGEN-RICH FIBRINOGEN

A 2% solution by weight of bovine plasma fraction I (Armour) was made in Veronal buffer saline.

This preparation of bovine fibrinogen contains plasminogen as a contaminant, and 40-60% by weight of sodium citrate.
The tissue-fibrin preparations were incubated for either 15, 30, or 60 minutes, and two samples were taken at the end of each period; thus six samples were examined from each block. In each preparation the degree of fibrinolytic activity of tissue components, ie, blood vessels, glandular epithelium, and secretion, was assessed in arbitrary units, using a semi-quantitative method (Kester, 1969) based on the magnification needed to detect the zones of lysis. An average value for the fibrinolytic activity was calculated for each type of component (Table II).

### Results

#### TESTIS

The scanty blood vessels in the tunica albuginea showed little fibrinolytic activity. Zones of lysis related to the seminiferous tubules (Fig. 2) were most uncommon, and were particularly related to areas of disruption of the germinal epithelium. No fibrinolytic activity could be detected around the spermatozoa within the lumen of the tubules.

#### EPIDIDYMIS

Epithelial activity was infrequent, random in distribution, and of only moderate intensity (Fig. 3). Spermatozoa and secretion again seemed inactive. The blood vessels in the epididymis and the remaining accessory organs showed consistent and striking activity.

#### VAS DEFERENS

Scattered sites of epithelial activity of moderate intensity were seen.

#### SEMINAL VESICLE

The epithelial surface often exhibited striking fibrinolytic activity. Scattered within the lumen of each crypt were many disrupted cells and fragments of cellular debris; the areas of lysis were often related to these (Fig. 4). Occasionally, foci of activity seemed related only to acellular secretions. The spermatozoa again seemed inactive.
Fig. 2  *Testis: fibrinolysis related to a seminiferous tubule. 60 min × 95.*

Fig. 3  *Epididymis: digestion of fibrin by tubular epithelium. 60 min × 122.*

Fig. 4  *Seminal vesicle: an area of digestion related to disintegrating epithelial cells. 30 min × 608.*
PROSTATE
Abundant zones of lysis, usually of moderate intensity, were related to the lining of the glands and ducts (Fig. 5) particularly where the epithelium was detached and presumably traumatized. Activity related to secretions was insignificant.

BULBO-URETHRAL GLAND
Of all the accessory organs, the bulbo-urethral gland showed the greatest levels of fibrinolytic activity. Figure 6 shows massive digestion of the substrate related to the glandular acini. The large ducts communicating with the urethra also exhibited conspicuous activity.

URETHRA
Figure 7 shows the vigorous fibrinolytic activity characteristic of urethral mucosa especially where there is epithelial disruption. Mild fibrinolytic activity was related to the urethral glands of Littré (Fig. 8).

Discussion
After examining the fluid obtained by prostatic massage, Huggins and Neal (1942) presumed that the source of seminal fibrinolysin was the prostate gland. Some doubt was cast on this deduction when Harvey (1949) showed that the fibrinolytic activity of seminal plasma was independent of the proportion of the prostatic component. Ying, Day, Whitmore, and Tagnon (1956) too thought that only part of the fibrinolytic activity of semen could be ascribed to prostatic secretion, especially since such secretion crudely obtained by prostatic massage would have some contribution from vesicular and urethral secretions. Karhausen and Tagnon (1955) attributed the fibrinolytic activity of the prostate to a trypsin-
like protease rather than to the presence of plasminogen activator. Although the prostate is rich in plasminogen activator (Albrechtsen, 1957; Rasmussen, Albrechtsen, and Astrup, 1958; Rasmussen and Albrechtsen, 1960), nevertheless the histological technique shows that the activator is largely confined to the vessels, making it unlikely that the prostate contributes much fibrinolytic activity to the ejaculate.

The normal secretory processes in male accessory glands are accompanied by definite changes in epithelial structure varying from desquamation to cell rupture (Mann, 1964). Analysis of the glandular fluid confirms the presence not only of whole epithelial cells but also of glandular debris. In the histological preparations, fibrinolytic activity related to such debris was conspicuous. This observation is consistent with that of Pandolfi and Astrup (1967) that damage or disruption of corneal epithelium enhances the fibrinolytic activity of these cells.

It has been shown in the present studies that the glandular epithelium of the male accessory genital organs contains plasminogen activator in varying amounts. Although the fibrinolytic activity of blood vessels is consistently high throughout the genital tract (except in the testis), the fibrinolytic activity of epithelium increases along the genital tract and is greatest in both the epithelium and secretion of Cowper's gland. The full significance of the fibrinolysis in seminal plasma is not yet clear. Since fibrinolytic activity may be necessary to maintain the patency of the urinary tract by digesting fibrinous deposits (Astrup and Sterndorff, 1952; Ladehoff, 1960; Charlton, 1966), fibrinolysis may
The distribution of plasminogen activator in the male genital tract

similarly be necessary to maintain semen in a fluid state within the genital passages (Mann, 1964). However, the high concentration of activator in the last secretion to be added to the ejaculate—that from Cowper’s glands—would suggest that the fibrinolytic activity had its main effects after ejaculation by liquefying the seminal coagulum and thus facilitating the migration of spermatozoa into the uterine cavity. It is also possible that plasmin plays a part in acrosome rupture, the process of 'sperm capacitation', and in penetration of the zona pellucida.

Huggins and Neal (1942) have shown that the fibrinolytic activity of semen was in the seminal plasma rather than in the spermatozoa; this has been confirmed using centrifugation methods checked by microscopy (Kester, 1970). In the present experiment no activator was demonstrated in spermatozoa, although Tymanidis and Astrup (1968) found that human spermatozoa in vaginal smears exhibited significant fibrinolysis. It is possible that in their material the spermatozoa were coated by seminal plasma containing activator, or that they had been activated by contact with vaginal or cervical secretions.

I am deeply indebted to Dr Alastair S. Todd for his continued interest and support, and to Mrs Anne Nunn for technical advice. I wish to thank Professor D. M. Douglas for laboratory facilities, Miss Mary Benstead, medical artist, for her assistance, Mr Tom King for his invaluable help in preparing the photomicrographs, and Miss Joyce Devlin for typing the script. I am grateful to the Board of Management, Dundee General Teaching Hospitals, for a research grant.
