SYNOPSIS The stability of thyroxine and triiodothyronine in serum has been investigated.

Apparent levels of total thyroxine, as determined by two different protein-binding assays employing thyroxine-binding globulin as the binding protein, increased significantly in serum and plasma samples stored at room temperature and were significantly lower in haemolysed samples. Values did not change significantly in samples stored at 4°C, nor in samples stored at room temperature when determined by radioimmunoassay. Total triiodothyronine levels, as determined by radioimmunoassay, fell slightly on storage.

Failure to appreciate the effect of storing samples at room temperature on apparent levels of total thyroxine, as determined by some protein-binding assays, could lead to an incorrect assessment of thyroid status.

There has been a rapid increase in demand for hormone determinations during recent years (Landon et al, 1974). Such assays are often technically complex and many require the use of isotope counting equipment. Thus, at present, many laboratories send some samples to specialized analytical centres. This has the disadvantage that several days may elapse between sample collection and assay, especially if there are postal delays or the sample arrives at the weekend. In addition, samples may be stored for several days at room temperature, sometimes unseparated or haemolysed, before despatch.

Thyroid disorders are among the commonest endocrine abnormalities encountered in clinical practice and, for this reason, the stability of thyroxine (T₄) and triiodothyronine (T₃) has been studied in blood samples obtained and stored under a variety of conditions similar to those that might be encountered in normal clinical practice. The effect of sample storage in the light and in the dark has also been investigated.

Materials and Methods

PRELIMINARY INVESTIGATION OF THE STABILITY OF TOTAL T₄ AND TOTAL T₃

Blood samples from each of six euthyroid subjects were divided into five aliquots, which were treated and stored for 48 hours under the conditions listed in the table. Total T₃ levels were determined by radioimmunoassay, total T₄ levels by a protein-binding assay (Thyopac 4), and the capacity to bind labelled T₃ was also assessed (THUT).

COMPARISON OF THE EFFECT OF STORAGE ON APPARENT SERUM TOTAL T₄ AND PROTEIN-BOUND IODINE LEVELS

Twenty millilitres of blood from each of two euthyroid subjects was allowed to clot at room temperature and the serum was separated and stored at room temperature in the light. Samples of the serum were removed after 0, 3, and 6 days and stored at −20°C before measurement of protein-bound iodine and total T₄ by the Thyopac 4 kit.

COMPARISON OF THE EFFECT OF STORAGE ON APPARENT SERUM TOTAL T₃ AND T₄ LEVELS AS DETERMINED BY DIFFERENT METHODS

Blood samples from three euthyroid subjects and from one clinically hyperthyroid patient were allowed to clot at room temperature, and the serum from each was divided into two aliquots, one of which was stored at room temperature and the other at 4°C. Samples were removed from each aliquot

at intervals and stored at \(-20^\circ C\). Total T4 levels were determined by the Thyopac 4 kit, by a resin protein binding assay, and by a radioimmunoassay. Total T3 levels were determined by radioimmunoassay.

**INVESTIGATION OF THE EFFECT OF LIGHT ON THE STABILITY OF TOTAL T4**

Blood samples were collected from 15 patients and allowed to clot at room temperature. After separation, each serum was divided into three aliquots, one of which was stored at \(-20^\circ C\). The other two were stored at room temperature for 14 days, one in the light, the other in the dark, and then stored at \(-20^\circ C\) until assayed by the Thyopac 4 kit.

**ASSAYS**

**Triiodothyronine**

A modification of the method of Mitsuma et al (1971) was employed using non-extracted serum and a goat antibody raised against a T3-human serum albumin conjugate. 8-Anilino-1-naphthalene sulphonic acid (ANS) was used to block the binding sites of thyroxine-binding globulin (TBG) and the antibody-bound and free fractions were separated with methyl cellulose coated charcoal. The 'within-batch' coefficient of variation was 4-4% as determined by 10 simultaneous analyses of a single pooled serum.

**Thyroxyine**

Total T4 was estimated by three methods:

1. A protein-binding assay based on the use of TBG (Thyopac 4 kit) was performed according to the manufacturer's instructions. T4 was extracted from the sample by addition of ethanol and equilibrated with TBG and labelled T4. Protein-bound and free T4 were separated by equilibration with adsorbent granules. The 'within-batch' coefficient of variation was 8-9% as determined by 10 simultaneous analyses of a single pooled serum.

2. A TBG-binding assay (resin assay) was used, which was a modification of the method described by Murphy (1965) and employed an anion exchange resin, Ag \(1 \times 2\) (Biorad Laboratories), to separate the bound and free fractions. A correction for the efficiency of ethanol extraction was made for each sample. The 'within-batch' coefficient of variation was 6-2% as determined by 10 simultaneous analyses of a single pooled serum.

3. A modification of the radioimmunoassay method of Chopra (1972) was employed, using non-extracted serum and a rabbit antibody raised against a T4-bovine serum albumin conjugate. ANS was used to block the binding sites of TBG, and the antibody-bound and free fractions were separated by a second antibody technique. The 'within-batch' coefficient of variation was 2-4% as determined by 10 simultaneous analyses of a single pooled serum.

**Thyroid hormone uptake test (THUT)**

The capacity of the samples to bind thyroid hormones was assessed by the Thyopac 4 kit (Radiochemical Centre, Amersham), performed according to the manufacturer's instructions. The samples were incubated with labelled T3, and the protein-bound and free T3 were then separated by equilibration with absorbent granules.
Protein-bound iodine

This was estimated by a Technicon Autoanlyser Mark I method with a 'within-batch' coefficient of variation of 4-0% (Chan, 1973).

Results

Preliminary investigation of the stability of total T4 and total T3

The results are summarized in the table in which the values obtained for aliquot 1 (heparinized plasma which had been separated and stored at -20°C immediately after collection) from each subject are used as a reference. Storage of plasma or whole blood, whether clotted or heparinized, for 48 hours at room temperature resulted in a significant increase of apparent T4 levels (approximately 20%) as determined by the Thyopac 4 kit. The presence or haemolysis (aliquot 4) resulted in a significant decrease in apparent T4 values of some 17%. Storage of plasma samples at room temperature caused small but significant losses in apparent total T3 levels from mean value of 2-21 to 1-99 nmol/l (aliquot 2). Similar decreases were also observed in aliquots 3 and 5, but haemolysis had no significant effect.

Storage at room temperature and haemolysis had no significant effect on the capacity of the aliquots to bind labelled T3, the results of the THUT assays on aliquots 2, 3, 4, and 5 ranging from 98-3 to 101-2% of aliquot 1.

Comparison of the effect of storage on apparent serum total T4 and protein-bound iodine levels

After six days' storage at room temperature the apparent serum total T4 levels of two subjects, as determined by the Thyopac 4 assays, increased from 91 to 121 and from 95 to 122 nmol/l. There was no corresponding increase in protein-bound iodine values, which remained at 66 and 58 nmol/l respectively.

Comparison of the effect of storage on apparent serum total T3 and T4 levels as determined by different methods

All serum samples stored at room temperature showed a continuous rise in apparent T4 content when determined by the Thyopac 4 and by the resin assay. Thus, with the former, all three euthyroid subjects, who had normal initial values, would have been diagnosed as thyrotoxic on the values obtained after storage of the samples at room temperature for two weeks. The resin assay showed less dramatic increases, but nonetheless levels increased into the thyrotoxic range in two of the three euthyroid subjects. There was no significant change in T4 values when the samples were measured by radioimmunoassay (fig 1). T4 levels remained constant in all samples stored at 4°C as determined by all three assays.

The apparent T3 levels in the serum of all subjects, as measured by radioimmunoassay, fell when stored either at room temperature or at 4°C. Thus, after one week at room temperature the mean T3 value had decreased from an initial level of 2-17 nmol/l by 19%, while over a similar period at 4°C the individual levels had decreased by between 12 and 15%.

Investigation of the effect of light on the stability of total T4

Similar results were obtained from samples stored in the light and in the dark. There was an increase in the apparent total T4 levels of all 15 samples after storage at room temperature for 14 days when compared with the control sample stored at -20°C. Figure 2 shows that the increase varied considerably from sample to sample; however, neither the actual nor the percentage increase was related to the initial total T4 levels.

Discussion

The most important finding in the present study is that the apparent total T4 levels in either plasma or serum samples stored at room temperature increase...
when measured by two different protein-binding assays, and that this increase varies considerably from sample to sample. No increase is observed when T₄ levels are measured by radioimmunoassay or when the protein-bound iodine is determined, indicating that T₄ itself is stable at room temperature and that the increase observed in the protein-binding assays is an artefact. Storage at 4°C provides a simple way of preventing this phenomenon but is not always possible, especially when samples are sent by post. Thus, misdiagnosis could easily occur due to hypothyroid values increasing into the euthyroid range or euthyroid values rising into the thyrotoxic range.

Other authors have observed similar increases in total T₄ levels after storage when measured by protein-binding assays. However, in contrast to this study, Watson and Lees (1973) and Badman and Platten (1973) suggest that the levels also increase in samples stored at 4°C when measured by the Thyopac 4 kit. The results of Frings and Hochholzer (1973), obtained using a protein-binding assay, agree with those of the present study.

Since the efficiency of ethanol extraction could increase after storage at room temperature, the extraction procedure was monitored by the addition of a trace amount of ¹²⁵I-T₄ to each serum sample before analysis. There was no increase in the recovery of the label. It was also possible that T₄ might be more unstable when stored in the light, therefore the total T₄ content of samples stored under conditions of light and dark was compared. No differences were observed.

The results suggest that at room temperature T₄ is stable, but that something is generated which interferes in assays employing TBG but not in more specific radioimmunoassays. The nature of this interfering substance was not investigated. It is ethanol extractable since both TBG-binding assays employ this as an initial step. Previous reports have shown that ethanol extracts obtained by the procedures described in this report contain both proteins (Goldie et al, 1974) and an unidentified substance thought to be a phospholipid (Irvine, 1974). One or both of these could interfere either by binding T₄ or by inhibiting the reaction between T₄ and TBG or the separating agent. Irvine found a substance present in ethanol extracts of serum which bound T₄ and thus caused a decrease in apparent T₄ levels. In the present study, however, we observed a progressive increase in apparent total T₄ levels on storage. It seems unlikely that the interfering substance would have the same effect on the resin and the absorbent granule separating agents, therefore inhibition of the reaction between T₄ and the binding protein seems the most probable explanation. Recently, Rootwelt (1975) has shown that there is a correlation between the increase in non-esterified fatty acids, which occurs on storage of blood samples at room temperature, and total T₄ levels measured by protein-binding techniques.

The apparent total T₃ content of both plasma and serum samples decreased on storage at room temperature and to a lesser extent at 4°C. Conversion of T₃ to T₄ is a possibility but cannot account for the apparent increase in T₄ levels, which is approximately 50 times greater than that of T₃.

Gross haemolysis led to considerable underestimation of T₄ levels by the Thyopac 4 kit. This was not due to dilution since the T₃ content of the same samples was not decreased significantly.

Radioimmunoassay would appear to be the method of choice for T₄ since by this method serum levels appear to be stable for at least two weeks at room temperature. Nonetheless, valid results may be obtained by TBG binding methods provided that samples are not haemolysed and are immediately stored at temperatures of 4°C, or lower, until assayed. Haemolysis appears to have no significant effect on total T₃ when measured by the radioimmunoassay employed in this study, but prolonged storage of samples either at room temperature or at
