Isolation of Staphylococcus aureus from sputum in cystic fibrosis

P. D. SPARHAM, D. I. LOBBAN, AND D. C. E. SPELLER

From the Bacteriology Department, Bristol Royal Hospital for Sick Children, Bristol BS2 8BJ, UK

SUMMARY The success in the isolation of Staphylococcus aureus of different methods of sputum processing was investigated in 60 specimens collected from 14 patients with cystic fibrosis during a seven-month period. Fifty specimens (83%) from 11 patients yielded Staph. aureus by one or more methods. Direct plating of purulent portions of sputum on to media designed for general use in respiratory infections gave unsatisfactory results (35% yield of Staph. aureus). Some increase in isolations was obtained with preliminary liquefaction of sputum; but the best results were given by the addition of a medium selective for staphylococci (mannitol salt agar, BBL) or by initial sonication of sputum (each 83% yield). Seven of the 11 strains of Staph. aureus were thymidine-dependent and otherwise atypical in laboratory characteristics; these were isolated from patients who had received co-trimoxazole.

In the respiratory infections of cystic fibrosis, Haemophilus influenzae, Staphylococcus aureus, and Pseudomonas aeruginosa have been recognised as the important pathogens (May et al., 1972; Mearns et al., 1972), and detection of their presence in sputum is essential for satisfactory antibiotic treatment. There is usually no difficulty with Ps. aeruginosa except that some strains require prolonged incubation before they produce recognisable colonies. Isolation of H. influenzae can be increased by the addition of a selective medium (Baber, 1969), which is used for all sputum specimens in this laboratory.

It was recognised, however, that the Staph. aureus strains present in sputa from these patients were not always fully defined in our laboratory reports. Typical staphylococci might be seen in a Gram film but not isolated or recognised in cultures. Some isolates failed to grow in antibiotic sensitivity tests. There appeared to be three reasons for this: the staphylococci were readily overgrown by other bacteria; their colonial appearances were often uncharacteristic; and some isolates were nutritionally deficient (Williams, 1977).

This investigation was undertaken to improve the methods for detection and characterisation of Staph. aureus. Selective and indicator media for staphylococci were compared, and the most discriminating was selected. The effect of sonication on Ps. aeruginosa and Staph. aureus was studied. The success of the laboratory’s routine methods for sputum culture was compared with the results of the introduction of the selective medium, of two methods of preliminary liquefaction of sputum, and of sonication of sputum.

Methods

COMPARISON OF SELECTIVE MEDIA

The following freshly prepared media were studied: milk agar (Christie and Keogh, 1940), salt milk agar (Cruickshank et al., 1975), polymyxin B agar (as in Cruickshank et al., 1975, except that the polymyxin was added finally to the medium when it had been autoclaved), tellurite egg yolk agar (Alder et al., 1962), and two brands of mannitol salt agar (MSA)-Oxoid and BBL.

The bacteria tested on these media were clinical isolates of Staph. aureus—both nutritionally normal strains and thymidine-dependent (thy-) strains isolated from patients with cystic fibrosis—Staph. epidermidis, Ps. aeruginosa, viridans streptococci, and Neisseria catarrhalis. Single colonies from pure cultures were inoculated into 10-ml amounts of heart infusion broth (HIB), which were incubated for 20 hours at 37°C. Viable counts were estimated by the method of Miles and Misra (Miles et al., 1938) with culture in triplicate on all selective media and on 5% horse blood agar. Colonies were counted at approx. 20 hours and at approx. 40 hours, because growth of staphylococci was slow on MSA and on tellurite egg yolk agar. Viable counts on the selective
media were expressed as percentage of the counts on the non-selective blood agar.

SONICATION
An MSE 150-watt ultrasonic disintegrator operating at 20 KHz, with a 3/8 inch titanium probe (McIntosh and Munro, 1971), was used. Volumes of 10 ml were treated in round-bottomed plastic containers, sealed with membrane, and immersed in an ice-bath.

Cultures (20-hour) of Ps. aeruginosa and Staph. aureus in 10 ml of HIB with 0·1% agar, and mixtures of the two, were subjected to sonication for periods of 0-5 minutes, and viable counts were performed, in triplicate, on Pseudocel Agar (BBL), a selective medium for Ps. aeruginosa containing cetrimide, and on MSA (BBL).

COMPARISON OF METHODS FOR CULTURE OF SPUTUM

Sputum specimens
Sixty specimens from 14 patients with cystic fibrosis were received in the laboratory during seven months. The patients, who were aged 3 to 16 years, were selected as having frequent outpatient attendances. The specimens were cultured by routine laboratory methods, with preliminary liquefaction and sonication, and on the selective medium.

Routine method for examination of sputum
Purulent portions were taken with a bacteriological loop, used to prepare a Gram-stained smear, and inoculated on to 5% horse blood agar, ‘chocolate agar’ with bacitracin 10 units per ml (Baber, 1969), and MacConkey’s bile-salt lactose agar. The plates were incubated for 20 hours at 37°C, the first two in air with 5% carbon dioxide, and the last in air. Plates yielding no growth were re-incubated for a further day.

Selective medium
Mannitol salt agar (BBL) was similarly inoculated and incubated in air.

Liquefaction
Sputa were treated by standard methods with pancreatin (Rawlins, 1953) and N-acetyl-1-cysteine (Airbron, BDH) (Mead and Woodhams, 1964).

Sonication (Williams, 1977)
Sputa in 10-ml volumes, or measured volumes made up to 10 ml with sterile distilled water, were treated for two minutes.

Liquefied and sonicated sputa were plated on the routine and the selective media and incubated as above. In addition, viable counts of Staph. aureus were estimated on MSA.

BACTERIAL IDENTIFICATION
Staph. aureus was identified by the slide-clumping factor test; negative strains were subjected to the tube coagulate test. Ps. aeruginosa was identified by the methods described by Phillips (1969).

THYMIDINE DEPENDENCE
Thy^- strains of Staph. aureus were detected by their failure to grow on media with low thymidine/thymine content, such as DST agar (Oxoid) with lysed blood. They showed satellitism around thymidine-impregnated discs on basal media, and were able to grow normally when 32 mg per litre thymidine was added to such media.

Results

The recovery of the various bacteria on different selective and indicator media is shown in Table 1. Milk agar and polymyxin B agar were unsatisfactory in allowing the growth of Ps. aeruginosa and of upper respiratory tract commensals. Salt milk agar was satisfactorily inhibitory but also partially suppressed the staphylococci, which were difficult to recognise on this medium. Tellurite egg-yolk agar required up to five days' incubation for recognisable growth of all Staph. aureus strains, and permitted some growth of Ps. aeruginosa. MSA inhibited Ps. aeruginosa and commensals satisfactorily, allowed
growth of staphylococci, and permitted presumptive distinction between \textit{Staph. aureus} and \textit{Staph. epidermidis}. Oxoid MSA, however, did not support the growth of thy\textsuperscript{−} \textit{Staph. aureus}. BBL MSA, which gave 100\% recovery of these strains, was therefore selected for further use.

The effect of sonication on cultures of \textit{Staph. aureus} and \textit{Ps. aeruginosa} is illustrated in Figure 1. \textit{Ps. aeruginosa} was almost completely destroyed at two minutes, while \textit{Staph. aureus} showed little decline from the original count at five minutes. The increase in colony-forming units during the first minute of sonication is presumably due to the breaking up of clumps of staphylococci (Huhtanen, 1966). This differential effect of sonication on a sputum specimen containing both bacteria is shown in Figure 2.

The total isolations of \textit{Staph. aureus} and \textit{Ps.}
*P. D. Sparham, D. I. Lobban, and D. C. E. Speller*

Of the 14 patients, 11 yielded *Staph. aureus* during the seven months of the investigation. Seven of the 11 strains were found to be thymidine-dependent. They were frequently bizarre in colonial form (Fig. 3) (Williams, 1977), and clumping factor negative but tube coagulase positive. They would not grow on DST agar, with or without lysed blood, nor on Oxoid MSA, nor on blood agar even when as little as 2.5% lysis of the blood had occurred. They produced small, often rough, colonies on BBL MSA. All seven patients who yielded thy⁻ *Staph. aureus* had previously been treated with co-trimoxazole. Thy⁻ clones could be produced in the laboratory from nutritionally normal *Staph. aureus* strains isolated from other patients, by growth in proteose-peptone broth containing 10 mg per litre trimethoprim.

**Discussion**

The routine methods used in this hospital group for the examination of sputum do not include the preliminary liquefaction of the specimens that has been adopted by most laboratories. A local survey of methods (unpublished) revealed that nine of 14 bacteriology laboratories in the South Western Region used some liquefaction method, while the others relied on the direct plating of purulent material. Wilkinson et al. (1977) showed that preliminary liquefaction did not have any advantage over direct plating in the examination of sputa from patients with clinical evidence of postoperative respiratory infection, provided that the selective medium for *H. influenzae* was included. In cystic fibrosis, however, the less usual respiratory pathogens, the prevalence of mucoid *Ps. aeruginosa* strains, and the characteristics of the staphylococci create special difficulties. It is clear that our routine method will not do for these specimens, and that liquefaction of sputum, by pancreatin or *N*-acetyl-1-cysteine, only partially solves the problems. Dilutions of the liquefied sputum were not cultured in this investigation, but it is unlikely that this would greatly improve the recovery of staphylococci. The method exerts no selective effect, and in almost all the specimens in this study there were at least 100 times more pseudomonas than staphylococci (colony counts).

The introduction either of sonication (Williams, 1977) or of a selective medium, however, gave equally great improvement in the isolation of *Staph. aureus* in the present study. BBL mannitol salt agar was by far the most satisfactory medium tested, for the selection and recognition of *Staph. aureus*, including thy⁻ variants, and has now been added to our routine methods for specimens from patients.

*aeruginosa* from the 60 sputum samples surveyed are given in Table 2. The viable counts of *Staph. aureus* (in the 50 specimens from which it was isolated by one or more method) after the two methods of liquefaction and after sonication are compared in Table 3. The numbers of instances in which each method yielded the highest viable count, those in which it yielded the highest count by a clear margin, and those in which no *Staph. aureus* was isolated, are given.

The comparative success in the isolation of *Staph. aureus* of the routine laboratory methods, of preliminary liquefaction or sonication of the sputum, and of the addition of the selective medium (MSA) is shown in Table 4. All the methods tested showed an improvement on the routine method, but the best result (83% positive) was obtained with sonication, or with the addition of MSA.

Isolation of Staphylococcus aureus from sputum in cystic fibrosis

with cystic fibrosis. This addition requires no new apparatus or procedures and is cheap in terms of materials and time. It does require two days' incubation, and the numbers of staphylococcal colonies isolated may be reduced.

Sonication, although it yielded the highest counts of Staph. aureus in the majority of cases, and produced an easily handled liquid specimen, is not recommended for routine use. It requires expensive apparatus, and as it destroys other important bacteria it has to be a separate additional technique. There are problems of overheating of samples, the production of aerosols, the need to sterilise the probe between runs, and distress to the operator from noise.

It must be emphasised that the successful use of any of these methods depends ultimately on the recognition of Staph. aureus when it is grown. Strains that have peculiar colonial forms, are clumping factor negative, or fail to grow on sensitivity testing media may be discarded by the unwary.

The use of co-trimoxazole is valuable in cystic fibrosis, especially in the treatment of H. influenzae infections in the presence of Staph. aureus, and long-term administration may prevent frequent relapse. The emergence of thy- Staph. aureus, however, must be expected. The pathogenicity of these strains has not been definitely established, but conditions in the respiratory tract should favour their normal growth (George and Healing, 1977).

In conclusion, it may be said that satisfactory recognition of Staph. aureus in the sputum of patients with cystic fibrosis requires either preliminary sonication or the use of a selective medium and, in either case, diligent and critical examination of the cultures.

We are grateful to the medical and nursing staff of the Bristol Children's Hospital for their interest and cooperation in these investigations, and to Dr R. Fraser Williams, Cystic Fibrosis Research Laboratory, Booth Hall Children's Hospital, Manchester, M9 2AA, for his continued advice and encouragement.
