Increased α-fetoprotein concentration in association with ileal adenocarcinoma complicating Crohn’s disease

M LEADER, JR JASS
From the Department of Histopathology, Westminster Hospital, London SW1P 2AR

SUMMARY A considerably raised serum α-fetoprotein concentration was found in a patient with an ileal adenocarcinoma. α-fetoprotein was shown in both the primary tumour and the hepatic metastases by an immunoperoxidase technique. A raised α-fetoprotein concentration in association with ileal adenocarcinoma has not been described previously, and it is notable that the first such case should occur as a complication of longstanding Crohn’s disease.

α-fetoprotein is a normal product of fetal liver and yolk sac. Small amounts may also be found in fetal gut.1 A raised serum α-fetoprotein concentration has been described in a variety of conditions, but concentrations above 1000 ku/l are unusual in all but primary hepatocellular carcinomas and germ cell tumours.2 We have found a considerably increased concentration in association with an ileal adenocarcinoma. Interestingly, the tumour arose as a complication of longstanding Crohn’s disease.

Case report

A 30 year old man with a 15 year history of Crohn’s disease presented with severe colicky abdominal pain. He had previously had several episodes of subacute intestinal obstruction, some of which necessitated admission to hospital. Each had responded to medical management. He had been maintained on low dosage prednisone for 13 years and intermittent azathioprine over the preceding four years.

On this occasion the clinical findings included those of small bowel obstruction, which responded to conservative treatment. But a new finding of gross hepatomegaly was also noted. Liver function tests showed a serum bilirubin concentration of 70 μmol/l, aspartate transferase 69 IU/l, alanine transferase 41 IU/l, and alkaline phosphatase 1500 IU/l. Ultrasound confirmed hepatomegaly and showed multiple echogenic areas consistent with metastases. A computed tomogram confirmed this impression.

A barium enema was essentially normal; a small bowel meal was not carried out.

α-fetoprotein estimation by radioimmunoassay (using a double antibody technique with polyethylene glycol assisted precipitation) showed an initial value of 8612 ku/l which quickly rose to 15540 ku/l (normal less than 10 ku/l). A diagnosis of a primary hepatocellular carcinoma or a germ cell tumour was therefore considered, but the testes were normal and there was no previous history of liver impairment. Carcinoembryonic antigen concentration was also raised at 963 μg/l (normal less than 10 μg/l) but β-human chorionic gonadotrophin was within the normal range.

A liver biopsy showed widespread infiltration by a moderately differentiated mucin producing adenocarcinoma. As mucin production is not a feature of primary hepatocellular carcinoma, this diagnosis, despite the high α-fetoprotein concentration, was discounted and a primary tumour of gastrointestinal origin was suggested. The patient deteriorated and died one week later.

POSTMORTEM FINDINGS

The salient features at necropsy concerned the liver and small intestine. The liver weighed 7710 g and 80% was replaced by white tumour deposits. The intervening parenchyma showed no evidence of cirrhosis. The lymph nodes at the porta hepatitis were not enlarged. The large intestine was normal, but both the jejunum and ileum showed patchy involvement of Crohn’s disease. The bowel wall was thickened and rigid and narrowed by multiple strictures (Fig. 1). The mucosal surface was roughened.

293
and granular and several inflammatory polyps projected into the lumen. Arising from one of the strictures in the distal ileum was a tumour measuring 5 cm in diameter (Fig. 1).

Histology confirmed the diagnosis of Crohn's disease. The mucosa was inflamed and showed patchy ulceration with occasional fissure formation. The mucus content of the glands was not depleted. The inflammatory polyps were composed of granulation tissue. Granulomas were not seen but pyloric type metaplasia of the glands was evident in the inflamed mucosa, the inflammatory polyps, and in the mucosa adjacent to the tumour (Fig. 2). The pyloric glands stained red with alcian blue/periodic acid Schiff-diastase, indicating the secretion of neutral mucins. The submucosa was oedematous and inflamed and showed an increase in fibrous tissue. It also contained rather prominent nerve trunks and collections of ganglion cells.

Histological examination of the tumour showed a moderately to poorly differentiated mucus producing adenocarcinoma, with a well marked glandular pattern in addition to more solid clumps of infiltrating cells (Fig. 3). Large sheets of tumour invaded
Increased α-fetoprotein concentration in association with ileal adenocarcinoma complicating Crohn's disease

Discussion

Abelev et al found the alpha globulin α-fetoprotein in mice in 1963. It is found in low concentrations in the serum of normal adults (5–10 Ku/l) and small rises occur in pregnancy. α-fetoprotein was initially thought to be a specific tumour marker of primary hepatocellular carcinoma, but with the advent of more sensitive radioimmunoassay techniques small rises in α-fetoprotein concentration were discovered in a variety of non-neoplastic liver diseases and tumours of the gastrointestinal tract, lungs, and prostate. Slightly increased concentrations have been described in association with carcinoma of the stomach, pancreas, biliary tree, and less commonly the colorectum. Ruoslahti et al reported a rise of >4000 Ku/l in a case of primary gastric carcinoma, and two papers report increased α-fetoprotein concentrations in patients with dual primary carcinomas of the stomach and prostate. Five cases of gastric carcinoma with liver metastases are reported in the French published work but values of α-fetoprotein are not given.

Increases in α-fetoprotein concentration to >100 times normal are exceedingly rare in gastrointestinal tract malignancies. McIntire et al report four such cases: one a colorectal carcinoma with a value of 50 000 Ku/l, and two cases of gastric carcinoma and one of a pancreatic carcinoma with values less than 10 000 Ku/l.

The occurrence of small bowel carcinomas in Crohn's disease was first described by Ginzburg et al. Over 60 such cases have now been reported, and Weedon et al and Greenstein et al found the increased incidence of small bowel carcinoma in this group to be significant. None of the reports of small bowel cancer have given α-fetoprotein values and the very high level in the case described here appears unique.

It is interesting to ask why a raised α-fetoprotein concentration should be associated with ileal adenocarcinoma complicating Crohn's disease. α-fetoprotein is a normal product of fetal liver and yolk sac, and small amounts may also be found in the gastrointestinal tract. It is well known that the principal gastrointestinal malignancies associated with a raised α-fetoprotein are those of the biliary system, stomach, and pancreas. Taken in conjunction with the liver, it would appear that malignancies of structures derived from the foregut show a particular association with α-fetoprotein production. Crohn's disease is often associated with foregut or more specifically pyloric metaplasia. This was noted in the present case, and, in addition, the adenocarcinoma showed certain morphological and histochemical similarities to gastric carcinomas of

pilorocardiac type. Foregut metaplasia could possibly be linked to the production of α-fetoprotein by the present case, but further examples of this phenomenon must be sought and studied.

We thank Miss Michelle Brooks and Miss Teresa Godden for typing this paper. We are grateful to Mr M Nelson for his photographic assistance. We also thank Dr Brian Gazzard, who looked after this patient.
