**Detection of Chlamydia trachomatis by enzyme immunoassay, immunofluorescence, and cell culture**

Muntaz *et al*¹ presented their evaluation of a commercial enzyme immunoassay (Abbott Laboratories) for detecting *Chlamydia trachomatis* in urethral and cervical specimens. The hospital and laboratory in which the work was performed has a long and well established research interest in *C trachomatis*. We present our experience with this enzyme immunoassay in a district general hospital that does not have such an established interest but wishes to provide a rapid and reliable service for the diagnosis of *C trachomatis* infection. We also simultaneously tested many of our patients using a third technique.

We evaluated 83 cervical specimens by enzyme immunoassay and a McCoy cell culture technique that was essentially similar to that described by Muntaz *et al*¹ except that cell monolayers were stained with Giemsa. Cell cultures were not passaged. Specimens were taken from women on their first visit to the clinic of genito-urinary medicine, irrespective of their reason for attendance. Fifty five of these patients were also tested by direct immunofluorescence using a fluorescein labelled genus specific mono-clonal antibody (Boots-Celltech Diagnostics). Specimens were considered to be positive if 10 or more fluorescing elementary bodies were seen. In each case the swab for enzyme immunoassay was taken before the swab for cell culture. If immunofluorescence was being performed the swab for culture was used to prepare a slide before it was placed in transport medium.

The Table shows the results. *C trachomatis* was isolated from 20 (24%) samples. Seventeen of these were positive by enzyme immunoassay. Of the three samples negative by enzyme immunoassay, one was positive by immunofluorescence. Two of the three cases that were negative by cell culture but positive by enzyme immunoassay were tested by immunofluorescence, and both were positive. None of the three patients whose samples were negative by cell culture had been treated with antibiotics in the few months before sampling.

Although the number of specimens evaluated was small, our results were similar to those of previous studies.¹-⁴ In addition, the results obtained indicate that specimens positive by enzyme immunoassay but negative by cell culture are not necessarily false positives but may represent the loss of viability of *C trachomatis* during transport. Our findings also raise some doubt about the use of cell culture as the "gold standard" and the value of defining a "specificity" (the number of healthy subjects with a negative test result divided by the total number of healthy subjects)³ for antigen detection assays.

If the enzyme immunoassay test is compared only with cell culture its specificity in our evaluation was 95% (60/63). Two of the three discrepant results were positive by immunofluorescence, and the third was not tested by this technique. If these results are taken to indicate that these two specimens were positive (and the third specimen disregard) the specificity of enzyme immunoassay may be considered to be 100% (60/60) in our small series. Similarly, the sensitivity of the enzyme immunoassay improves from 85% (17/20) to 86% (19/22) compared with a sensitivity for cell culture of 91% (20/22). Therefore, sensitivity and specificity figures must be interpreted with caution when the reference test is known to have a sensitivity of less than 100%.

In conclusion, although under ideal conditions cell culture may be more sensitive than enzyme immunoassay, in routine diagnostic use this is probably balanced by the failure to isolate *C trachomatis* from several infected patients. The use of such an enzyme immunoassay has resulted in a considerable improvement in our service, as we no longer encounter the problems of maintaining a cell line of required sensitivity for the reliable isolation of *C trachomatis*.

During the autumn of 1983 a policy of limited antibiotic reporting was adopted by the senior medical staff of the microbiology department of Leeds General Infirmary. This policy called for the laboratory to suggest the use of single agents that were considered to be less toxic, less expensive, or less likely to cause bacterial antibiotic resistance, for the treatment of inpatient, outpatient, and general practitioner patients, from whom a significant isolate had been obtained. A laboratory report for a patient with uncomplicated urinary tract infection would normally indicate the susceptibility of the isolate to trimethoprim, sulphonamides, and nitrofurantoin. Alternative antibiotics would be reported if indicated by the clinical condition of the patient. For this scheme to be effective full clinical details of the patient are required by the laboratory. Completed laboratory reports therefore carried comments indicating to the clinician the importance of clearly stating the patient's condition, the duration of illness, length of pregnancy if applicable, and any recent or current treatment with antibiotics, whether or not prescribed for urinary tract infection. Antibiotics prescribed for other conditions may be excreted in adequate quantities in the urine to preclude the isolation of a clinically important organism, although urinary tract infection itself may persist.

Hospital clinicians normally respond to advice given by the laboratory on the use of antibiotics; there is, however, some doubt about the influence of the laboratory on the prescribing patterns of general practitioners. To determine the influence of the limited antibiotic reporting policy on the prescribing habits of general practitioners a survey was carried out by the laboratory shortly after the policy was introduced and repeated twelve months later. The survey entailed asking general practitioners for their preferred antibiotic for use in the treatment of urinary tract infection; a laboratory method monitored incoming urines for content and subsequent identification of antimicrobial substances.1

In the winter of 1983–4 a questionnaire was issued to 149 general practitioners within the western Leeds area to whom the Infirmary laboratory is responsible for the handling of specimens. Twelve months later the questionnaire was reissued and the responses compared. The questionnaire described six circumstances in which a general practitioner might find him or herself when dealing with a patient presenting with symptoms of urinary tract infection. Each question asked the general practitioner to indicate his choice of antibiotic. The content

Influence of laboratory sensitivity reporting on antibiotic prescribing preferences of general practitioners in the Leeds area

A survey made over two periods of time was used to determine the effect of a limited antibiotic reporting policy on the prescribing habits of general practitioners in the Leeds area.
