SUMMARY A method for the simultaneous demonstration of lysozyme and mucins in 39 cases of gastric adenomas differentiated two intermediate cell types. The first was similar to a columnar cell comprising a single cell population which covered extensive areas of the adenomas. This cell type often showed supranuclear lysozyme reactivity and apical neutral mucins, sialomucins, and sulphomucins in variable amounts. The second cell type was found in 11 adenomas, located mainly in the fundal area. It seemed to be a transitional form between the goblet cell and the Paneth cell. This cell type was scattered among columnar cells, occasional Paneth-like cells, and small goblet cells. These two types of intermediate cells may be regarded as abnormally differentiated integral elements of gastric adenomas. They may be associated with the neck stem cells in the cytogenesis of gastric adenomas.

Lysozyme is a bacteriolytic enzyme present in human milk, tears, saliva and serum. It has been detected by immunohistochemical techniques in a variety of human cells and tissue.1-4 In the gastrointestinal tract lysozyme is found in the normal epithelial cells of the oesophageal submucosal glands, fundal and pyloric glands, Brunner’s glands and Paneth cells. Mucin-producing cells containing lysozyme have been also described in the small intestine of normal rats and patients with inflammatory bowel disease.5-6 Furthermore, mucin-secreting tumour cells containing lysozyme have been observed in gastric carcinoma.7,8 The purpose of this study was to investigate whether intermediate cells were present in gastric adenomas which produce lysozyme and mucins at the same time.

Material and methods

The ages of the 39 patients ranged from 50 to 91 years (median 75 years). The sex distribution was unequal, with 26 men and 13 women. Thirty nine gastric adenomas were examined histopathologically from material obtained at operation in 20 cases and by endoscopic polypectomy in 19 cases. All specimens were fixed in 10–20% formalin and embedded in paraffin wax.

Serial sections were stained with haematoxylin and eosin, periodic acid Schiff (PAS), alcian blue, pH 2.5, and high iron diamine.

For the detection of lysozyme, the peroxidase-antiperoxidase (PAP) technique9 was used with antibodies obtained from Dakopatts (Copenhagen, Denmark). Serial sections 5 μm thick were treated serially for 30 minutes with: (i) 0.1% hydrogen peroxide in methanol; (ii) non-immune swine serum; (iii) rabbit anti-human lysozyme serum (dilution 1/200); (iv) swine anti-rabbit globulin antiserum (dilution 1/50); (v) rabbit anti-horseradish PAP complexes (dilution 1/100). Peroxidase activity was shown with the 3,3′-diaminobenzidine tetrahydrochloride (Sigma) reaction described by Graham and Karnovsky.10

To evaluate the specificity of the lysozyme staining9 the primary antiserum was replaced by phosphate buffered saline, normal rabbit serum, or absorbed at 4°C for 24 hours with purified 90% protein-lysozyme (10 nmol) extracted from chicken egg white (Sigma Chemical Co).

The simultaneous presence of lysozyme and mucosubstances in the same tissue section was shown by applying the PAP method for the demonstration of lysozyme followed by either PAS or alcian blue. The high iron diamine (HID) method was also applied to serial sections to characterise the sulphomucin positive cells containing lysozyme.

Intestinal metaplasia was divided into types I, Ia, and Iib.11 Histological definition of papillary, tubular, and papillotubular adenoma was made according to the WHO classification.12 Grading of dysplasia was limited to mild and severe grades as it was based on purely subjective criteria.

Adenomas with a focus of adenocarcinoma were excluded from the present study.

Lysozyme and mucins in gastric adenomas

Results

The male: female ratio was 2 : 1. Cases were concentrated in the older age groups, peaking in the seventh decade. Primary location was as follows: 20 (51%) cases in the antral region; 17 (43%) cases in the fundal region; two (5%) cases in the cardiac region. Thirty cases were solitary adenomas. In three, adenomas were associated with gastric ulcers; in six cases early gastric cancer was also evident at the same time.

The adenomas were polypoid lesions in 15 (38-5%) cases (fig 1) and flat or slightly raised in 24 (61.5%) cases. The size of the lesions ranged from 0.3 to 2 cm.

Twenty-four (61.5%) cases were tubular adenomas and 15 cases (38.5%) papillotubular adenomas. They were usually composed of two different glandular structures (fig 2). The lower layer contained pyloric-type glands of normal appearance or intestinal-type tubules; both types showing cystic dilatation to a variable degree (fig 2). The upper layer comprised dysplastic foveolar tubules. Mild dysplasia was found in 16 (41%) adenomas and severe dysplasia in 23 (59%) adenomas.

Mildly dysplastic foveolar tubules were lined by goblet cells and tall columnar cells. Goblet cells secreted sialomucins or sulphomucins, or both. Columnar cells contained neutral mucins, sialomucins, and sulphomucins in varying proportions; their mucin positivity was located on the luminal surface or in the apical portion of the cytoplasm.

Severely dysplastic foveolar tubules were lined by a monomorphic population of columnar cells showing elongated or rounded nuclei with prominent nucleoli. Occasional, small goblet cells were irregularly distributed and secreted a mixture of sialomucins and sulphomucins. In 11 out of 39 adenomas, all of which showed severe dysplasia, there were Paneth-like cells showing cytoplasmic eosinophilic granules, which were stained purple with the alcian blue-PAS stains. Other cells of a similar appearance had PAS positive granular elements in the supranuclear cytoplasm and aggregates of alcian blue positive material in the apical cytoplasm.

LYSOZYME IMMUNOREACTIVITY IN ADENOMAS

In mildly dysplastic foveolar tubules lysozyme immunoreactivity was weak and limited to some columnar cells. In severely dysplastic foveolar tubules columnar cells showed a moderate to strong lysozyme staining in the supranuclear cytoplasm (fig 3). Paneth-like cells were scattered among columnar cells in severely dysplastic areas in 11 adenomas, located in the fundal region (n = 10) and in the antral region (n = 1). These Paneth-like cells showed a lysozyme positivity in granular elements within the apical and supranuclear cytoplasm.

When the histochemical methods for mucins were applied either as a counterstain or on serial sections to those stained immunohistochemically for lysozyme, a supranuclear positivity for lysozyme (figs 4 and 5) and an apical secretion of a variable amount of neutral mucins (fig 5), sialomucins, and sulphomucins (fig 6) could often be seen lining severely dysplastic tubules in columnar cells.

The simultaneous demonstration of alcian blue and lysozyme reactivity on the same tissue sections also allowed intermediate Paneth-goblet cells to be identified in 11 adenomas, 10 of which were located in the fundus and one in the antrum. Some of these intermediate cells showed a lysozyme positivity in coarse and fine granules in the supranuclear cytoplasm, whereas in the apical cytoplasm there was an

Fig 5  Intense supranuclear lysozyme positivity is evident in dysplastic columnar cells. (PAP technique.)
aggregation of alcian blue positive material (fig 7). Lysozyme positive granular elements were interspersed among alcian blue positive mucin droplets in the cytoplasm.

In the lower layer subjacent to the adenoma type IIa, incomplete intestinal metaplasia was commonly observed but some lysozyme positive Paneth cells were also demonstrable in five adenomas in the fundus (fig 3). Lysozyme immunoreactivity was found in numerous epithelial cells of cystically dilated glands.

Discussion

Most adenomas were located in the antral (51%) and fundal regions (43%) with a few in the cardia (5%). Adenomas were polypoid in 38.5% and flat or slightly raised in 61.5%. Histologically, they displayed a tubular (61.5%) or papillotubular growth pattern (39.5%).

Paneth-like cells have been observed morphologically and immunohistochemically in gastric adenomas. The combination of standard histochemical staining with immunohistochemical techniques allowed more than one differentiated function in a cell to be identified at light microscopic level. Not only were Paneth-like cells shown, but also intermediate cells between small, goblet cells, and Paneth cells in 10 adenomas situated in the fundus and one in the antrum. Fundal mucosa was more likely to be the site of the adenomas with Paneth-like cells and intermediate Paneth-goblet cells than the antral mucosa. This close topographical relation was also found by Ito et al., who showed that tubular adenomas in the fundus contain numerous Paneth cells as does fundal intestinal metaplasia. This was also confirmed by our finding a small number of Paneth cells in the non-neoplastic mucosa lying just below five adenomas located in the fundal region. Paneth-goblet cells have been described ultrastructurally or immunohistochemically in samples of small intestine from normal rats and patients with inflammatory bowel diseases. It has consequently been suggested that both these epithelial cells may have a common precursor. The presence of Paneth-goblet cell hybrids suggests an abnormal differentiation of these intestinal-type epithelial cells in gastric adenomas.

Our findings of goblet cells, Paneth-like cells, and intermediate Paneth-goblet cells in adenomas further support the intestinal metaplastic nature of the lesion, as suggested by several other authors.

In normal human stomach lysozyme may usually be found in neutral mucin-secreting cells of the antral and fundal glands as well as in mucus neck cells, which produce small amounts of neutral mucins, sialomucins, and sulphomucins. The adenoma columnar cells, particularly in severely dysplastic
foveolar tubules, show a clear polarisation of lysozyme reactivity in the supranuclear cytoplasm and small amounts of neutral mucins, sialomucins, and sulphomucins in the apical cytoplasm. Our findings suggest that these abnormally differentiated columnar cells reproduce the partially differentiated mucous neck cells of the normal proliferative zone, retaining or modifying some of their functional characteristics. On the other hand, cell kinetic studies have shown that gastric adenomas arise from the neck stem cells of the mucosa, as in the case with intestinal metaplasia. Thus lysozyme producing, mucin positive columnar cells, as well as Paneth-goblet cells, may have their origins in the partially differentiated neck cells of the gastric mucosa.

In conclusion, the combination of standard histochemical and immunohistochemical techniques for showing lysozyme reactivity allows abnormally differentiated, intermediate cell populations to be identified in gastric adenomas, a disease in which cellular turnover is greatly increased.
