Inverted hyperplastic polyposis of the colon

N A Shepherd

Abstract
Aims: To describe and evaluate two apparently unique cases of inverted hyperplastic (metaplastic) polyposis of the colon.
Methods: The cases were analysed by standard histopathological, histochemical, and immunohistochemical techniques and the findings compared with those of regular hyperplastic polyps of the colorectum.
Results: Both patients were middle-aged men with concurrent adenocarcinoma of the proximal large intestine. The inverted polyps numbered 18 and 12, measured between 0.4 and 2.5 cm in diameter, and were all present in the proximal ascending colon. The polyps had characteristic macroscopic features: they were positioned on the apex of mucosal folds and demonstrated surface pitting and mucus hypersecretion. Histologically, inversion and misplacement of hyperplastic epithelium was related to lymphoglandular complexes. The polyps showed all the histochemical and immunohistochemical features of regular hyperplastic polyps.
Conclusions: Inverted hyperplastic polyps are an unusual but distinctive polyp of the proximal colon, may be multiple, and share the phenotypic changes of regular hyperplastic polyps. The pathogenesis of epithelial inversion probably relates to misplacement of epithelium through anatomical defects in the muscularis mucosae due to mechanical forces. The polyps may mimic both adenomas and carcinomas. The neoplastic potential of inverted hyperplastic polyposis is likely to be very low: one polyp only showed adenomatous change.

Case reports
CASE 1
A 68 year old man presented with a three month history of anal bleeding and iron deficiency anaemia. There was no relevant medical or family history. A barium enema and subsequent colonoscopy demonstrated a caecal tumour which was shown on biopsy to be an adenocarcinoma. There were two polyps, each 0.5 cm in diameter, in the distal colon: both were mildly dysplastic tubular adenomas. Elective right hemicolecystomy was performed. The patient was followed up as an outpatient and remained well for nine months after surgery with no signs of tumour recurrence.

CASE 2
A 62 year old man presented as an emergency with generalised abdominal pain, a high fever, and signs of small intestinal obstruction. There was no relevant medical or family history. At emergency laparotomy a 5 cm appendiceal mass was discovered with evidence of perforation of the caecum and an acute generalised peritonitis. There was extensive intraperitoneal tumour spread. A palliative extended right hemicolecystomy was performed with defunctioning ileostomy and mucus fistula. Despite the extensive tumour, the patient remained well four months after surgery.

Pathology
All material was received fresh in the laboratory. Resection specimens were opened, pinned out on a corkboard, and fixed in 10% buffered formalin. Tissues were routinely processed through paraffin wax. Sections were cut at 4 μm and stained with haematoxylin and eosin, periodic acid schiff, Perl’s stain and high iron diamine alcin blue (HIDAB), the latter according to the method of Spicer. Sections were stained using the avidin-biotin complex immunohistochemical method with the monoclonal antibodies carcinoembryonic antigen (CEA: Dakopatts), IgA (α chain; Dakopatts), and secretory component (SC: ICRF, London). Sections with normal colonic mucosa, hyperplastic polyps, and carcinoma served as positive controls. For negative controls primary antibodies were excluded.

CASE 1
The right hemicolecystomy comprised 2 cm of terminal ileum, caecum with a 9 cm appendix, and 13 cm of ascending colon. Arising in the caecum was an ulcerating tumour 6.8 × 6.3 cm (fig 1). In the ascending colon within 8 cm of the ileocaecal valve were a total
CASE 2
The specimen consisted of 11 cm of terminal ileum, caecum with a 5 cm tumour mass replacing the appendix, and 55 cm of proximal colon. The ileum appeared normal. The ileocaecal valve showed lipohyperplasia. The entire colonic serosa was covered by fibrinous exudate with numerous small tumour nodules. In the proximal ascending colon were a total of 18 polyps. These were transversely orientated on the free edges of mucosal folds. They measured between 0·6 cm and 2·5 cm in diameter. They showed very similar macroscopic appearances to the polyps in specimen 1 (fig 2) with a pitted surface and evidence of excessive mucus secretion. The polyps were strictly localised to the proximal 15 cm of the ascending colon and there were no further mucosal lesions in the more distal colon.

Histological and histochemical findings
All 30 polyps in both cases showed the architectural, cytological and proliferative features characteristic of hyperplastic polyp. One polyp in case 1 showed a focus of adenomatous epithelium with mild dysplasia adjacent to hyperplastic change, although despite serial sectioning, continuity could not be demonstrated. No other polyp showed such divergent features. In all polyps there were exophytic components characteristic of regular hyperplastic polyp, but in addition all polyps of case 2 and all but three of case 1 showed areas of endophytic growth in which epithelium was embedded in submucosal tissues deep to the muscularis mucosae. Some of these foci took the form of tubules with the characteristic hyperproliferative basal region and serrated maturing epithelium intimately mixed with submucosal connective tissues (figs 3 and 4). Other foci showed the same cellular content but the architecture was grossly distorted by massive mucin hypersecretion and entrapment with the formation of submucosal mucin cysts (fig 5). Mucin hypersecretion was also evident in the mucosal component of these polyps and resulted in a cap of haematoxyphilic mucin on the surface of the polyp (fig 6). Apart from the one focus of tubular adenoma in a polyp of case 1, dysplastic features were entirely absent. In several foci of endophytic growth, particularly those in which there was relatively early inversion, epithelial misplacement was clearly related to lymphoglandular complexes (fig 3 and 6).

All inverted hyperplastic polyps showed the same characteristic mucin histochemical and immunohistochemical profile as that seen in classic hyperplastic polyps. Thus siaiomucin was strongly expressed (staining blue with HIDAB), and there was enhanced immunostaining for CEA (fig 7) and diminished staining for SC and IgA in inverted hyperplastic polyps compared with normal colorectal mucosa. Haemosiderin was not demonstrated adjacent to any misplaced epithelium in the Perls preparations. The presence of invasive adenocarcinoma was confirmed in both cases. The caecal tumour of case 1 was a moderately
colonic preponderance, the predominance of female patients, and their histological mimicry of both adenomas and carcinomas of the colon.7 This study clearly shows that such polyps can be multiple and appear to be predominantly situated in the proximal ascending colon: in neither case was there evidence of similar polyps in the more distal colon. This study further shows a characteristic macroscopic appearance with a pucked and pitted surface (presumably the result of underlying epithelial misplacement), surface mucus hypersecretion, and underlying mucous cysts. The latter feature parallels those of colitis cystica profunda in which epithelial misplacement in solitary ulcer syndrome and allied conditions results in submucosal mucous cysts.8

In this study the inverted hyperplastic polyps showed morphological, histochemical, and immunohistochemical features identical with those of regular hyperplastic polyps of the sigmoid colon and rectum.9 They appear to represent the same dysmature and hypermature colonic mucosal lesion5 and, like regular hyperplastic polyps, inverted hyperplastic polyps are concentrated on the apices of the mucosal folds. The prime difference between regular hyperplastic polyps and their right-sided equivalents is the frequency of epithelial misplacement and mucus hypersecretion. Another striking feature of these ascending colon polyps is their relatively large size. Most regular hyperplastic polyps measure under 0.5 cm,5 while Sobin records examples of inverted hyperplastic polyps measuring 1.5 cm in diameter,9 and in this study several measured in excess of 2 cm. Could the inversion be solely the result of the size of these polyps? This is most unlikely as both small and large polyps showed the features of inversion in this study and epithelial misplacement is not a feature of giant hyperplastic polyposis.10

What is the cause of the epithelial inversion? Epithelial misplacement is seen in several situations in polyps and other lesions of the intestines. Torsion with mucosal necrosis is the pathogenetic mechanism of epithelial misplacement (pseudo-invasion) in pedunculated adenomas, particularly of the sigmoid colon.12 The absence of haemosiderin in areas of inversion argues against this mechanism as a cause of epithelial misplacement in hyperplastic polyps. Colitis cystica profunda in solitary ulcer syndrome of the rectum and other conditions in which mucosal prolapse is the pathogenetic mechanism is the result of mucosal erosion and regeneration.10 13 14 Such inflammatory changes are not observed in inverted hyperplastic polyps. In Peutz-Jeghers syndrome up to 10% of small intestinal polyps show epithelial misplacement.15 Obstructive forces with intussusception lead to raised intraluminal pressures and the likely result of this is that the excessive epithelium of the polyps is forced through anatomical defects in the wall of the intestine.16 In inverted hyperplastic polyps the epithelial misplacement is seen closely related to lymphoid glandular complexes, structures which are associated with an

differentiated Dukes B adenocarcinoma with extensive extramural venous spread but no evidence of spread to the peritoneal surface. In case 2 the appendiceal tumour was a poorly differentiated adenocarcinoma, with evidence of serosal pathology and transcoelomic spread.

Discussion
Sobin's description of solitary inverted hyperplastic polyps emphasises their right-sided
Just one polyp in the cases under study showed adenomatous change. Such mixed hyperplastic-adenomatous polyps are thought to be associated with malignant potential, but nothing is known of the risk factors for the condition. There is some evidence to suggest that larger hyperplastic polyps are more likely to show foci of dysplastic/adenomatous epithelium. Both cases in this study were associated with proximal large intestinal carcinomas but both patients were within the expected age range of such tumours and one at least had a considerably enhanced risk by having two distal colonic adenomas. The inevitable conclusion is that the malignant potential of inverted hyperplastic polyposis is very low and primarily relates to the presence or absence of an associated adenomatous component.

Can the term polyposis be justified for these two cases? In general the term is reserved for syndromes in which large numbers of polyps are present within the bowel. However, some polyposis syndromes, in particular Peutz-Jeghers and juvenile polyposis, may be associated with relatively low numbers of polyps. Indeed, 10 or more polyps of the juvenile type is an accepted definition for juvenile polyposis. Inverted hyperplastic polyposis would seem an appropriate term, although it is recognised that these polyps represent a distinctive form of hyperplastic polyp with a characteristic endophytic growth pattern rather than a separate entity. The recognition of the characteristic macroscopic and histological features of these polyps will ensure that
there is no confusion with other polyposis syndromes and will avoid erroneous diagnoses of adenoma and carcinoma of the proximal colon.

Inverted hyperplastic polyposis of the colon.
