Evaluation of the LCR based assay for detecting C. trachomatis

517

sensitivity of the LCR kit is identical with that of the PCR kit and that the LCR kit can detect two or more EBs per assay. The average number of plasmids in one EB was estimated to be about 10. These results, therefore, indicate that 20 copies or more of the plasmid can be amplified and detected by the LCR kit under the conditions used. Dille et al. reported that the sensitivity of the LCR kit which targets the major outer membrane protein gene and the plasmid appeared to be three EBs per assay using purified EBs which were counted by optical microscopy with Giemsa staining. Their results lead us to wonder whether the accuracy of the particle counting, together with the purity of the EB fraction used in their tests, were sufficient for this highly sensitive assay.

C. psittaci has also been reported to contain plasmids, but they were not amplified in either of the assays used in the present study, indicating the sequence differences between C. trachomatis and C. psittaci. No evidence was obtained for the presence of plasmids in C. pneumoniae organisms isolated from humans.

In conclusion, the newly developed LCR test kit, which can be used as a non-radioactive method, is extremely sensitive and specific for the detection of C. trachomatis organisms. The manipulation procedures for this assay are simple and designed to minimise carry-over contamination which can cause false positive results. Therefore, we recommend the LCR and PCR kits for the routine diagnosis of C. trachomatis infection.

Abstract

A case of late stage cutaneous leishmaniasis with focal caseous necrosis is reported. The patient, a 30 year old Tunisian man, presented with idiopathic bone marrow aplasia. Microscopically, minimal changes were observed in the epidermis: slight hyperkeratosis and moderate acanthosis. Lesions predominated in the dermis. Epithelioid granulomas were found in the lower dermis. Some of these lesions were clearly surrounded by a ring of lymphocytes and were rarely confluent. A peculiar histological feature was the presence of focal acidophilic and slightly granular necrosis at the centre of some the tuberculoid lesions. Focal fibrinoid necrosis was found in the upper dermis, outside granulomas. A mild to moderate infiltrate of histiocytes, lymphocytes and plasma cells, with scanty neutrophils, was observed mainly in the upper dermis. No intracellular or extracellular Leishman–Donovan bodies were observed. Acid fast mycobacteria, however, were not detected. Leishmaniasis was diagnosed on culture of skin biopsy specimens. The presence of caseous necrosis could lead to diagnostic confusion and result in an erroneous diagnosis of, for example, tuberculosis, syphilis, acne agminata, and sarcoïdosis with fibrinoid necrosis. This is especially the case when parasites are scanty or absent.

Keywords: cutaneous leishmaniasis, caseous necrosis, pathology.

Cutaneous leishmaniasis, caused by infection with a flagellate protozoan, is endemic in the Mediterranean region. The disease can occur in one of four clinical forms: acute leishmaniasis, chronic leishmaniasis, leishmaniasis recidivans, and diffuse cutaneous leishmaniasis. Ninety per cent of cases of acute cutaneous leishmaniasis resolve without treatment, healing with scar formation. The remaining cases generally evolve into chronic disease.

Acute and chronic leishmaniasis can manifest clinically as papular, nodular, plaque-like, or most commonly, ulcerated lesions, usually located on skin exposed to the sun.\(^6\) \(^7\)

On histological examination, acute leishmaniasis generally appears as macrophage lysis in the centre of macrophagic granulomas, which are usually associated with numerous lymphocytes and plasma cells. Chronic leishmaniasis—that is, late stage leishmaniasis, has been well characterised histologically\(^8\) \(^9\) and commonly presents as tuberculoid lesions without necrosis. However, there is no fundamental distinction between the tuberculoid lesions of chronic cutaneous leishmaniasis and the later stages of its acute counterpart.\(^10\)

**Case report**

A 30 year old Tunisian man was referred to our institution for treatment of idiopathic bone marrow aplasia. Physical examination disclosed multiple and confluent cutaneous lesions on the patient's left elbow and back (fig 1). The lesions had been spreading for several months, and were crusted and surrounded by gradually spreading erythema and induration. A diagnosis of cutaneous mycobacteria infection was proposed on the basis of skin biopsy findings and antituberculous treatment was started. A few weeks later, culture of the biopsy specimen yielded promastigote forms of leishmania. Bone marrow aspiration and duodenal biopsy were done. Culture remained negative for leishmaniasis. Skin tissue culture was negative after treatment with amphotericin B, despite the presence of iatrogenic immunodepression. Serological tests were negative for leishmania.

**Pathological findings**

The skin biopsy specimens were fixed in Bouin's liquid and embedded in paraffin wax. Serial sections, 3–4 \(\mu\)m thick, were stained with haematoxylin–safronin, periodic acid-Schiff (PAS) reagent, Ziehl–Neelsen, Giemsa, and Gomori-Grocott stains.

Minimal changes were observed in the epidermis on microscopic examination—that is, slight hyperkeratosis and moderate acanthosis. Lesions predominated in the dermis. Epithelioid granulomas were found mainly in the lower dermis. Some of these lesions were clearly surrounded by a ring of lymphocytes and were rarely confluent. A peculiar histological feature was the presence of focal acidophilic and slightly granular necrosis at the centre of some tuberculoid lesions (fig 2). Focal fibrinoid necrosis was found in the upper dermis, outside granulomas. A mild to moderate infiltrate of histiocytes, lymphocytes and plasma cells, with scanty neutrophils, was observed mainly in the upper dermis. No intracellular or extracellular Leishman–Donovan bodies were seen on haematoxylin–eosin–safronin, and Giemsa stained sections. No acid fast mycobacteria were observed on Ziehl–Neelsen stained sections. No refringent material was detected under polarised light. Microorganisms were not seen in sections stained with PAS and Gomori-Grocott.

**Discussion**

This present case of late stage cutaneous leishmaniasis is unusual because of the presence of focal caseous necrosis associated with tuberculoid lesions in the lower dermis. The histopathology of cutaneous leishmaniasis has been described extensively\(^8\) \(^9\) and the later stages of acute leishmaniasis and the chronic form of the disease are usually characterised by tuberculoid infiltrates in the dermis.\(^8\) \(^9\) \(^10\) To our knowledge, caseous necrosis has not been described previously in the skin, but has been reported previously in lymph nodes.\(^10\) Septic necrosis has been observed in skin biopsy specimens and attributed to the presence of concomitant infection with Vincent's organisms,\(^14\) *Streptococcus viridans*, other saprophytic streptococci, or *Candida albicans*.\(^15\) Bacterial, mycobacterial and fungal cultures were negative in the present case. However, fibrinoid necrosis, which is visually different from caseous necrosis, is common in acute leishmaniasis\(^16\) but less so in the chronic form.\(^10\)

The development of tuberculoid lesions seems to be caused by expansion of a T cell subset producing interleukins 3 and 4 and...
Carcinosarcoma arising in a dermoid cyst of the ovary

D S Arora, S Haldane

Abstract

A case of carcinosarcoma arising within an otherwise benign cystic teratoma is reported. The patient, a 78 year old nulliparous woman, presented with right sided abdominal pain of short duration and subsequently underwent a bilateral salpingo-oophorectomy. Slicing of the left ovary revealed a unilocular cyst containing hair admixed with soft yellow material with a thin wall apart from a solid area at one pole. Extensive areas of necrosis and cystic degeneration were present within this mass. Histologically, the large cyst was a typical mature cystic teratoma, containing carcinomatous and sarcomatous elements. Mature cystic teratomas have been reported in association with a variety of malignant ovarian tumours such as mucinous cystadenocarcinoma and malignant germ cell neoplasms. Secondary malignant transformation within a dermoid cyst is a much rarer occurrence, estimated as less than 2% of all such lesions. Adenocarcinomas are the second most common malignancies arising within dermoid cysts. Sarcomas alone or in combination with squamous carcinoma have been described arising in a mature cystic teratoma. To the best of our knowledge, no case of sarcoma arising in association with adenocarcinoma has been described before.

Keywords: ovary, dermoid cyst, carcinosarcoma.

Malignant transformation within a mature cystic teratoma (dermoid cyst) occurs in less than
