Protocol for ultrarapid immunostaining of frozen sections

Thomas Richter, Jörg Nährig, Paul Komminoth, Jürgen Kowolik, Martin Werner

Abstract
Rapid immunostaining of frozen sections within a tolerable time span would be very helpful for intraoperative diagnosis. A protocol was therefore established using the enhanced polymer one-step staining (EPOS) system (Dako) with antibodies against leucocyte common antigen (LCA), cytokeratin (CK), and anti-melanoma (MEL). Best results with reliable and specific immunostaining and a labelling intensity comparable to standard immunostaining protocols were achieved with fixation of samples in 100% acetone for 20 seconds (CK, LCA) or two minutes (MEL), followed by incubation of the primary antibody and development of the chromogen reaction with 3,3′-diaminobenzidine (DAB) for three and five minutes at 37°C, respectively. The total procedure takes only 12 minutes, thus enabling rapid immunostaining on intraoperative frozen sections. Apart from its use in tumour classification, this method is especially useful in detecting tumour cells in sentinel lymph nodes.

Keywords: immunohistochemistry; frozen sections; EPOS; sentinel lymph node

In frozen sections the distinction between lymphoma, carcinoma, malignant melanoma, sarcoma, and chronic inflammation may be difficult on a morphological basis alone. Immunohistochemistry can often resolve this problem, but for intraoperative cryosection diagnosis, standard immunostaining methods require a time span which cannot be tolerated in the operating room. Another important setting in which rapid immunostaining would be helpful is to confirm or exclude tumour clearance in resection margins or to detect micrometastases in sentinel lymph nodes—for example, the axillary sentinel lymph nodes in breast cancer patients or regional lymph nodes in patients with malignant melanoma.1 2

Although acceleration of immunostaining has been achieved by the use of high quality reagents,1 preformed antibody–avidin–biotin–peroxidase complexes,2 or microwave oven treatment during incubation of reagents,2 6 these methods have not proven suitable for routine diagnosis and frozen sections. The enhanced polymer one-step staining (EPOS) system, where primary antibodies and horse-radish peroxidase (HRP) are linked to a chemical inert polymer complex (dextran),7 offers a one step immunostaining procedure.7 The polymer complex has been shown to be resistant to microwave treatment, which can be used to accelerate the incubation time.4 7

We have established a rapid and reliable immunostaining protocol with EPOS monoclonal antibodies. This protocol is easily accomplished, delivers fast and reproducible results, and is therefore applicable to intraoperative frozen sections.

Methods
Fresh tissues were obtained within 10 minutes after surgical removal. Specimens comprised six lymph nodes (three normal, two metastases of colon carcinomas, and one metastasis of a malignant melanoma), three carcinomas of the breast, stomach, and colon, as well as two malignant melanomas and two fibroadenomas of the breast. An additional 19 sentinel lymph nodes from 15 breast carcinoma patients were also investigated. Detection of the sentinel lymph nodes was done by technetium-99m labelling.2 Frozen sections (7 µm) were mounted on silane coated glass slides.

We compared different fixatives (4% buffered formaldehyde (pH 7.0), 100% methanol, 4% formaldehyde/100 % methanol 1:1, 100% acetone), and variable fixation times (20 seconds, two minutes, five minutes), with or without subsequent air drying of the sample. Slides were then rinsed for 15 seconds in Tris buffered saline (TBS, pH 7.4).

The prediluted EPOS reagents and antibodies against leucocyte common antigen (LCA), cytokeratin (CK), and anti-melanoma (MEL) (LCA/HRP (CD45, clone 2B11+PD7/26), anti-CK/HRP (clone MNF116), and anti-MEL/HRP (clone HMB45)) were kindly provided by Dako and incubated for one, three, or five minutes at room temperature or at 37°C in an incubation chamber. Incubation in a microwave oven (power output 500 W) was tested for 30 seconds, 2 × 30 seconds, one minute, or 2 × one minute.

The developmental step of the chromogen reaction (Dako HRP kit) was carried out again at room temperature, at 37°C in a incubation
chamber, or in a microwave oven (power output 500 W) for one, three, or five minutes, respectively. During microwaving the slides were cooled by a cold water bath. All treatments that were tested are summarised in table 1. During incubation at 37°C in the incubation chamber, drying of the samples was prevented by covering the slides with a small coverslip.

All reactions were compared with standard immunostaining on serial sections of the material fixed in formaldehyde and paraffin embedded, using the same monoclonal antibodies and a HRP/DAB detection kit (Dako peroxidase/DAB detection kit; code No K 5001). One serial section from sentinel lymph nodes was stained with haematoxylin and eosin (H&E) for routine diagnosis.

Results

For immunostaining with CK and LCA, fixation of the frozen sections was optimal with
two minutes of 4% formaldehyde fixation or 20 seconds of 100% acetone fixation. Preservation of morphology was slightly better with formaldehyde fixation. Fixation in ethanol and the formalin/ethanol mixture led to faint staining with CK and LCA.

Incubation of the EPOS reagents at room temperature for one, three, or five minutes showed specific staining of the target cells, but signal intensity was always reduced compared to standard immunostaining. Incubation at 37°C for three minutes, in combination with DAB development at 37°C for five minutes, showed excellent preservation of morphology with strong and specific immunostaining, slightly reduced compared with standard immunostaining in serial sections. Microwave heating during incubation of the EPOS reagents resulted in specific antibody binding by 30 seconds. Staining intensity reached an optimum at 60 seconds, and staining for periods longer than 90 seconds produced non-specific binding and tissue shrinkage. Overall, with microwave accelerated incubation, morphology was less well preserved than with the other treatments, but still delivered consistent results. Application of our protocol (table 2) to sentinel lymph nodes of breast cancer patients detected metastases in five of 15 patients positive by both rapid standard immunohistochemistry and immunohistochemistry, while only four patients were positive with H&E stains. Figure 1 shows the results of rapid immunostaining with CK, MEL, and LCA and an example of the application to sentinel lymph nodes of breast cancer patients.

Discussion

The EPOS system is a synthetic, high polymeric glucopolysaccharide (dextran) with chemically bound primary antibody and enzyme (HRP) molecules. In spite of the high molecular weight, even a few minutes of incubation at room temperature results in sufficient immunostaining, as shown here for CK, LCA, and MEL, and also for proliferating cell nuclear antigen and Ki-67 antigen by Tsutsumi et al.10 The reaction may even be accelerated with heating during incubation. Microwave heating, as proposed by Chilosi et al.,8 was less optimal in our hands because of decreased preservation of the morphology. Moreover, incubation in the microwave oven was very sensitive to incubation time and power setting. We suggest incubation of both the EPOS reagents and the developmental step at 37°C, which results in stronger staining compared with incubation at room temperature and produces fewer artefacts than occur with incubation in a microwave oven.

Fixation with acetone for two minutes, as proposed by Chilosi et al.,8 did not improve the staining intensity except in the case of MEL. Blocking of endogenous peroxidase (2% H2O2, one minute) was not necessary in our specimens (data not shown), but may be needed when tissue samples from the gastrointestinal tract, tissues with haemorrhage, or tissues with infiltrates of neutrophil granulocytes are investigated.10

Table 2 summarises the optimal protocol for rapid immunostaining using the EPOS system. This protocol is easily accomplished within a few minutes and since all reagents are prediluted and ready for use no special experience in immunohistochemistry is necessary. The antibodies applied—for example, CK, LCA, and MEL—are helpful for the many differential diagnostic problems that may be encountered in intraoperative frozen sections, as well as for ascertaining tumour clearance at resection margins. Our first results on axillary sentinel lymph nodes in breast cancer patients show that rapid intraoperative immunostaining of frozen sections with CK increases the detection rates of micrometastases (paper in preparation).

Protocol for ultrarapid immunostaining of frozen sections.
