Rationalised virological electron microscope specimen testing policy

I read the two letters from McCaughey and Curry and their respective colleagues with astonishment. Their debate on a policy for electron microscopy (EM) use reminded me of those mediaeval ones about the number of angels that could dance on the head of a pin. Interesting debate, pity it missed the point. They failed, I think, to address three important aspects:

1. The nature of virus diagnosis. No one can pretend that virus laboratories can investigate every individual ‘viral’ illness in the community, but they have an obligation to monitor what is prevalent in it. Although attractive to a cash strapped service, selecting specimens on the basis that some are more likely to yield positives than others misses the point of diagnosis—more than one virus can cause many ‘virus like’ syndromes and virus detection does not parallel exactly the presence of symptoms. To discard specimens taken from those who are recovering because the yield may be low, or where the cause is apparently obvious, strikes me as arrogant. If someone has taken the trouble to send a specimen, it seems reasonable to look at it, if only in the hope that the sender might be encouraged to send others in the future, although if it turns out to be positive. It is a constant battle to get worthwhile virological specimens sent to the laboratory—choking them off is daft. Moreover, I would further confirm the Irish view that solid stools may often yield positives and also that making the diagnosis by holding the specimen up to the light (metaphorically speaking) is very important. Trends in infection can only be given some credence if the specimen base remains more or less constant. Arbitrary and variable selection of what will be examined, and what will not, becomes less effective for each specimen the more it is used, but this use must be sensitive, and humane to the operator.

2. The question of money. EM is unique among virological laboratory techniques in that the major costs of using it diagnostically (equipment, staff) are incurred in setting it up in the first place. Running costs, in comparison, are trivial, but savings are thought to be possible by allowing the operator to work only part time. Used full time, the technique becomes less expensive for each specimen the more it is used, but this use must be sensitive, and humane to the operator. Microscopy, and EM in particular, can never really be a part time occupation— the operator needs to keep in constant practice and to be committed to it. The cream of his/her work should not be skimmed off by using other techniques (enzyme immunoassays, etc.)—to detect rotavirus or adenovirus—for example. Like everyone else, electron microscopists thrive on getting positive results and these reward immensely what can be a lonely working existence. Moreover, the laboratory gets several simultaneous tests for its money, results are produced more quickly than with other tests and, in most cases, with greater accuracy.

3. The need to retain EM as a non-centralised resource. With changes in travel and climate, ‘new’ viruses can appear anywhere at any time. Part of characterising a putative new virus, whether truly novel or merely transferred to a new habitat, is to know what it looks like—other properties correlate surprisingly well with structure and having only a national, or even a regional, facility for this purpose is usually a recipe for serious delay. Specimens from the periphery do not carry the same urgency as the facility’s own work, especially if the latter has to meet internal performance targets. Passing perhaps the most interesting part to another laboratory is hardly likely to encourage the local virus hunters either.

Clamping EM into a “rational policy”, instead of encouraging its use wherever possible, will ultimately cause it to die a slow death from a downward spiral of discouragement. Put in rugby terms, use it or lose it. EM is the only truly “catch all” technique in diagnostic virology. If lost, it will be replaced (partially, even at best) with a battery of tests which, collectively, will cost more, take longer to do, and will frequently miss the dual or triple infections that are common in children.

C R MADELEY
Barrow, Stocksfield, Northumberland, NE41 7TN, UK

The authors reply

McCaughey’s perception of the continuing usefulness of diagnostic electron microscopy (EM) in virus laboratories is very different from ours. We believe that diagnostic EM is becoming largely redundant and will continue to be replaced by other methods. Increasingly, these alternatives are molecular. Such assays are preferable to EM on grounds of cost, sensitivity, and the inherent versatility of generic methodology. In our laboratory, we have replaced EM as our routine first line test for adult cases of gastroenteritis with nested reverse transcription polymerase chain reaction (RT–PCR) for small round structured virus (SRSV). We have replaced EM as the first line test for skin material with a multiplex nested PCR for herpes simplex virus (HSV) types 1 and 2 and varicella zoster virus (VZV).

This approach has yielded a sixfold increase in sensitivity over EM.1 Madeley appears to confuse the cost of expensive commercial molecular assays with that of much more economical in house assays. The change from the use of EM and virus isolation to nested PCR in our laboratory was on the basis that the latter approach was more economical, in addition to the improved assay performance.2 A typical reagent cost for our in house nested PCR assays would be less than £3, including extraction, and the manpower costs are considerably less than for traditional methods.3 The cost of EM is not “trivial”; the man hours spent are a valuable resource that can be used more productively within the diagnostic laboratory.

Molecular assay delivery does not require operators with more training or experience than traditional methods such as EM, virus isolation, and antigen detection. The use of generic methodology simplifies the training and skill mixes required to provide a comprehensive service compared with that required for a service delivered via diverse traditional methods.

The term “catch all” was first applied to diagnostic EM in the 1970s and is now inappropriate. EM is insensitive and non-specific. Our nested multiplex PCR assay can distinguish between HSV-1, HSV-2, and VZV in a slide from a vesicular skin lesion. EM will often miss the diagnosis, and even when positive will only indicate the presence of a virus from the Herpesviridae family. In 30 years of diagnostic EM we have not discovered any new viruses. In the first year of routinely using nested PCR on all skin specimens we have discovered a deletion mutant of HSV type 1. Looking for new viruses via routine diagnosis is not a function of a diagnostic virology laboratory. Producing results that affect patient management and infection control in an efficient, timely, and economic fashion is a major function.

If Professor Madeley considers the rewarding aspect of diagnostic virology to be the positive result, then he should welcome the availability of more sensitive methodology. There is a responsibility for diagnostic laboratories continuously to improve their performance, rather than to continue with assays whose appeal is aesthetic rather than functional.

The authors reply

Professor Madeley’s comments are very welcome but his letter opens up the debate about electron microscopy (EM) to a much greater extent than that originally intended by either the rationalised EM policy paper1 or the recent correspondence relating to it.2 We strongly agree that EM should not be allowed to wither and die, but maintaining the relative abundance of EM units that existed into the late 1980s was untenable for two main reasons. First, the development of new investigative and diagnostic technologies (initially

www.jclinpath.com

enzyme immunoassays and subsequently the polymerase chain reaction) and secondly financial pressures that have affected, not only the PHLS, but also hospital pathology departments and universities. Both these factors have meant that the use of EM in many centres has been critically reviewed. Many universities have centralised their EM facilities into units either specialising in materials science or biomedical science. Within pathology, many laboratories have given up locally provided EM services because of cost considerations and buy only the EM services that they require from established units, which is more cost effective than maintaining a local EM facility. Within the PHLS, a strategy for EM was formulated, which resulted in the formation of a strategic network of EM units in England and Wales being retained. This rationalised EM service provided significant improvements in virus surveillance and showed—for example, the true importance of small round structured viruses (SRVs) as a cause of outbreaks of gastroenteritis in the UK.

A fundamental limitation of EM is that every specimen needs individual examination by a skilled microscopist. This aspect of EM cannot be automated and restricts the number of specimens that can be examined by a microscopist within a working day. Only through the speed that warrant individual attention should be examined, and this is at odds with Professor Madeley’s view that if a specimen is submitted it should be examined. Newer diagnostic methods are very sensitive, much cheaper for each test, can handle greater numbers, and often require less skilled staff to perform them. It is because of such developments that EM would no longer be considered as a front line tool for—for example, group A rotavirus.

Professor Madeley also makes the point that EM is relatively cheap after the initial capital investment. However, this is over simplistic because microscopes and associated ancillary equipment all have finite lives. Even if an electron microscope were in operation for 20+ years, few organisations would have the money to replace such an instrument on anything like a cost to one basis. Even the remaining microscope units, the cost of annual maintenance contracts for such instruments is high, and when taken with the limited number of specimens that can be examined and the costs of a skilled electron microscopist, this means that a virological examination costs tens of pounds to perform. It is because of such developments that EM would no longer be considered as a front line tool for—for example, group A rotavirus.

The report by Millar and colleagues of aberrant expression of CD10, the common acute lymphoblastic leukaemia (ALL) antigen, by the cells of a marginal zone non-Hodgkin’s lymphoma (NHL) is important because it reminds histopathologists not to rely too heavily on the results of single surface marker tests. ‘Aberrant’ expression of CD antigens by malignant lympho-haemopoietic cells is a phenomenon with which haematologists have long been familiar; expression of ‘myeloid’ antigens CD13 and CD33 by the blast cells of common ALL and the ‘B lymphoid’ antigen CD19 by those of acute myeloid leukaemia with the (8:21) translocation are two classic examples. But is not the range of CD10 positive NHL cases already rather broader than they suggest? We have known for years that up to 20% or so of lymphoblastic lymphomas have an immunophenotype indistinguishable from common ALL and that a similar proportion of other lymphoblastic lymphomas, albeit not acknowledged by the REAL classification, may also express CD10. In addition, the REAL classification also points out that some cases of mantle cell and diffuse large B cell lymphoma express CD10.

The range of monoclonal antibodies that work superbly on sections of formalin fixed, paraffin wax embedded tissue is steadily expanding. The wider use of comprehensive panels of antibodies in the diagnosis of NHL, whether on sections or by flow cytometry or both, will surely reveal more ‘aberrant’ results, and may even modify our views about what ‘aberrant’ means.

Aberrant CD10 expression by NHL

In the current climate of adverse publicity and a UK manpower crisis in histopathology, the book’s aim to “project the pathologist and break some of the myths surrounding his profession” is most welcome. Dr Anim appears well qualified to undertake such a task, having worked in Kuwait, Ghana, and London, and having experience in the four main pathology disciplines. Despite being a histopathologist, he succeeds in minimising the niggly fixation of most accounts and gives a considered overview of each branch of pathology, highlighting the often overlooked educational and management aspects of the job.

The book comprises a brief history of pathology and its subspecialties, analyses various training schemes and practices worldwide, and touches on future developments. It is more than just a factual account because the author puts forward opinions on the role of pathology in the undergraduate curriculum, the need for close clinical liaison, and the frustrations experienced by pathologists trained abroad who return to work in less developed countries.

The author acknowledges that some of his observations on training might be deficient owing to the speed of recent modifications which, not surprisingly, is the case in his coverage of the MRCPath examination. Mention of the specialist training register and the concept of continuing medical education are notable omissions.

There are several appendices pertaining to training in the UK, USA, China, and the USSR, but these would benefit from the inclusion of contact addresses/web sites for organisations such as the RCPath, ACP, IBMS, and IAP and their overseas equivalents. Although the information in the text seems up to date, the references are disappointing, with many citations of recent trends/advances dating from the mid-eighties.

The price is extremely reasonable, which encourages one to overlook the occasional typographical errors such as “the part 2 is less formal and may consist of a dissertation!”

In my opinion, the author achieves his aim and this book will be of value to those called upon to explain the work of a pathologist to health professionals or lay people, and to those involved in giving careers advice.

Joanna S Johnson

Atlas of Tumor Pathology: Tumors of the Upper Aerodigestive Tract and Ear.

Mills SE, Gaffey MJ, Frierson HF. (h50.00.) Armed Forces Institute of Pathology, 2000. ISBN 1 881 04157 3.

The upper aerodigestive tract comprises the ear, nasal cavity, paranasal sinuses, oral cavity, pharynx, and larynx. The 26th fascicle in the third series of the atlas of tumor pathology, which is published by the Armed Forces Institute of Pathology, forms a reliable guide when facing the diagnostic challenges raised by diseases in these areas. The colleagues Mills, Gaffey, and Frierson, all well known for their expertise in the area of head and neck pathology, have been successful in creating a book
CD-ROM review

I am a lover of well written textbooks and, I suspect, like most histopathologists a relatively late adopter of new technologies such as the use of the digital image. I therefore faced the review of this CD-ROM atlas of surgical pathology with some trepidation—the reader should take this into account. This CD-ROM installs, or uses, Quick Time, Adobe Acrobat, and Folio Bound Views to present and navigate between what is stated to be over 4000 images taken from 1500 different lesion types. The images are almost all haematoxylin and eosin stained sections. The quality of photomicrography is good—illumination is even, the staining is not obviously faded, and there are no colour casts. The colour intensity is rather strong and occasionally slightly muddy. The resolution of the images is not obviously stated, but is such that a full screen image looks good, without obvious pixellation, but when the zoom in facility is used, the pixellation becomes obvious when the magnification has been increased by 50% or more. There is obviously a “learning curve” with the manipulation of digital images, and I found the exercise very difficult compared with direct microscopy of slides. The main reason appeared to be the slight over emphasis on high power images, the inability to select one’s own field, and the lack of resolution compared with real microscopy. On the positive side, however, was the requirement to make a commitment to a diagnosis on the basis of a given field. This is obviously something that could be used in the future for testing professional interpretation in a very standardised way.

All of this raises the question “who would derive most value from the program?” I don’t think there is a lot of new information here for existing consultants. However, I can imagine the images being useful in teaching (I should note that I attempted to cut and copy some of the images out of the program, without knowing whether I am allowed to or not, but in any event, the program would not allow me to do this). Trainees might prefer this to a paper atlas because a large number of reasonably high quality images are contained here, and the indexing is fine for someone used to navigating electronic indexes. However, they would need to be at a level where they know the names of basic histological patterns. I would therefore envisage that this would be invaluable to SpRs as an adjunct to viewing slide collections and participating in bench work.

I would recommend that departments setting up an electronic learning resource for their trainees add this to the collection of available CD-ROM programs and think that practical use would be seen at least by those trainees who enjoy operating this type of technology.

Practical Adult Cardiovascular Pathology Course
6–8 November 2000
Royal Brompton Hospital, Imperial School of Medicine, and National Heart and Lung Institute

This “hands on” course approaches in detail the problems that face the diagnostic pathologist when dealing with cardiovascular pathology. Congenital heart disease will be highlighted. The approach to a cardiac necropsy and sudden death will be emphasised. Cardiac specimens will be made available for analysis and practical demonstrations as well as video demonstrations. A slide seminar is also included. The course is aimed at trainees studying for the MRCPATH and also senior pathologists who wish to update their knowledge of cardiac disease, both congenital and adult. Course fee £300.00 or £200.00 for juniors in training.

Details from: Short Course Office, National Heart and Lung Institute, Dovehouse Street, London SW3 6LY; tel: +44(0)20 73518172; fax +44(0)20 73518246; email: shortcourse.nhli@ic.ac.uk

TIM STEPHENSON

www.jclinpath.com

The authors would like to apologise for an error that occurred in this paper. It was stated throughout the paper that 665 children were tested but in fact the number was 669. In addition, in the first sentence of the results section of the abstract 530 of 691 (87%) should be 530 of 619 (86%). The authors stress that these errors do not change the message of the paper.
Rationalised virological electron microscope specimen testing policy
