Inflammatory pseudotumour associated with chronic persistent *Eikenella corrodens* infection: a case report and brief review

S-H Lee, Y-C Fang, J-P Luo, H-I Kuo, H-C Chen

Inflammatory pseudotumour is an uncommon mass forming lesion, representing the histological expression of an infective or reactive reparative process (pseudotumour) in most cases, and a bona fide neoplasm (for example, inflammatory myofibroblastic tumour) in a minority of cases. This report describes the case of an inflammatory pseudotumour with a pathology that unveiled proliferative CD68 positive and actin negative spindle shaped cells, with a mild mixed inflammatory infiltrate, and a culture that yielded an uncommon fastidious bacillus, *Eikenella corrodens*. The clinical course was indolent but protracted, with insidious progression to multifocal non-contiguous lesions, involving the lungs, liver, spleen, left kidney, and deep neck tissue, all of which responded to medical treatment with appropriate antibiotics. It is of paramount importance that clinicians search for an infective cause of an inflammatory pseudotumour, to ensure appropriate treatment.

Inflammatory pseudotumours (IPTs) have long been accepted as an aberrant or exaggerated response to tissue injury undergoing a chronic inflammatory process. Although IPTs usually have a benign evolution, with the occasional documented infective cause, the prognosis of a minority of cases is poor, and includes local recurrence, development of multifocal non-contiguous lesions, infiltrative local growth, vascular invasion, and malignant transformation, which seems contradictory to their purely inflammatory or reactive nature. This nosological category, which pathologists and clinicians have long been convinced of, is enigmatic and has recently resulted in the introduction of a plethora of alternative terminology for this fibroinflammatory disorder, including inflammatory myofibroblastic tumours (IMFTs), *Eikenella corrodens* is a rarely isolated Gram negative, facultatively anaerobic, fastidious bacillus. Although it is part of the normal flora of the human oral cavity, upper respiratory tract, and gastrointestinal and genitourinary tracts, its potential to act as a pathogen has been well documented.

‘‘Although inflammatory pseudotumours usually have a benign evolution, with the occasional documented infective cause, the prognosis of a minority of cases is poor’’

We report a case of IPT with a protracted neoplasm-like clinical course and culture isolated *E corrodens*, with the aim of alerting physicians to this uncommon opportunistic pathogen, the need for an appropriate antibiotic coverage, and the role of *E corrodens* as a possible aetiological agent in a still incomplete list of microorganisms implicated in IPTs with an infective origin.

**CASE REPORT**

A 46 year old woman initially presented to our pulmonary medicine clinic complaining of a productive cough with intermittent blood tinged sputum for more than six months’ duration. She had a known history of oesophago-gastrectomy, with colon bypass for the treatment of chemical corrosive injuries caused by a suicide attempt more than one year before. Chest computerised tomography (CT) revealed consolidation in the left lower lobe of the lung, with volume reduction and several small low attenuated lesions in the spleen. She had no fever (37°C orally) and showed leucocytosis (15.62 × 10^3/μl) and neutrophilia (87.4%) in the peripheral blood. Serum carcinoembryonic antigen (CEA) was normal (2.2 ng/ml). Bronchoscopy disclosed an elevated lesion with surface erosion on the left main bronchial mucosa. Endobronchial biopsy showed acute suppurative inflammation, without granuloma or malignancy. Echo guided transpleural left lung biopsy revealed chronic inflammation and interstitial fibrosis, without granuloma or malignancy. Acid fast stains for mycobacteria in the sputum, bronchial washing/brushing specimens, and pulmonary biopsy tissue were all negative. She received a seven day course of oral kitasamycin (a macrolide antibiotic) and conservative symptomatic treatment before being lost to follow up.

The patient presented again to our gastrointestinal medicine clinic less than one year later as a result of intractable pain over the right upper abdomen and right lower chest. Sonography revealed two right hepatic masses and right lower lung consolidation. CT showed irregular heterogeneously enhancing masses in the right lower lung, a large irregular mass, measuring 9 × 7 × 4 cm, alongside several small irregular nodules, visible with heterogeneous contrast enhancement in the right liver (fig 1), in addition to several small irregular nodules with similar characteristics in the left kidney and spleen. The left pulmonary lesion present one year earlier had resolved. A low grade fever (up to 37.7°C orally) and moderate leucocytosis (16.00 × 10^3/μl) with neutrophilia (87.4%) in the peripheral blood were present, although there were no toxic signs of sepsis. Serum CEA (3.74 ng/ml) and α fetoprotein (19.4 μg/litre) were also normal. An amoebic haemagglutination test was negative. Blood bacterial culture and sputum mycobacterial culture revealed no growth. An acid fast stain of the sputum for

**Abbreviations:** CEA, carcinoembryonic antigen; CT, computed tomography; IMFT, inflammatory myofibroblastic tumour; IPT, inflammatory pseudotumour
mycobacteria remained negative. Echo guided, core needle biopsy and fine needle aspiration of the liver were finally performed for pathological and microbiological studies to elucidate the multifocal and seemingly recurrent lesions. Histopathology of the liver mass biopsy showed proliferation of benign spindle shaped cells and a minor component of inflammatory cells, consisting of lymphocytes, plasma cells, histiocytes including xanthomatous cells, neutrophils, and eosinophils (fig 2), not greatly different from that seen in the previous lung biopsy, which disclosed acute and chronic inflammation with fibrosis. The impression was one of a chronic abscess with an exaggerated granulation tissue response. However, the hepatic mass showed a soft tissue density with heterogeneous contrast enhancement, instead of a water density with a well enhanced rim, which is usually seen in typical hepatic pyogenic or amoebic abscesses. It also yielded a scanty amount of fluid, in contrast to the usual abscess aspirate, and there was a clinical impression that it might be a metastatic neoplasm. A constellation of colony characteristics and biochemical assays indicated that the organism was *E corrodens*, and antibiotic sensitivity testing proved that it was susceptible to cefixime, cefotaxime, ceftizoxime, cefpodoxime, ampicillin, ciprofloxacin, and amoxicillin-clavulanate, and resistant to sulfamethoxazole-trimethoprim. Echo guided transpleural biopsy of the right lung was also performed and showed a similar fibroinflammatory lesion, with an identical immunohistochemical profile to the lesions found in the liver and left lung. The patient initially received intravenous amoxicillin-clavulanate and was discharged after improvement.

Unfortunately the patient revisited our otolaryngology clinic one month later, presenting with a left submandibular mass and mild fever (37.3°C orally). The peripheral blood revealed mild leucocytosis (white blood cell count, 10.66 x 10³/µl) with neutrophilia (82.2%). Neck CT showed a strongly and heterogeneously enhancing mass, measuring 2.7 x 1.7 cm, located inferior to the left mandibular angle. Again, biopsy disclosed a similar histopathology to the previous lesions, and an identical immunohistochemical profile. Intravenous amoxicillin-clavulanate was administered. The patient was followed up without recurrence for more than 19 months, during which CT showed nearly complete resolution of all the lesions in the lungs, liver (fig 1), spleen, and kidney.
DISCUSSION

_Eikenella corrodens_ is a rare contributor to liver abscess,¹ in that the most frequently isolated pathogen in our microbiology laboratory during the past decade was _Klebsiella pneumoniae_. It is a fastidious, slow growing, human commensal bacillus, capable of acting as an opportunistic pathogen and causing abscesses in several anatomical sites, including the liver,³–⁶ lung,⁷ spleen,⁷ and submandibular region,⁷ as demonstrated by our present case. The patient’s previous oesophagogastric bypass with colon bypass for her corrosive injuries may have contributed to bacterial spreading via the damaged gastrointestinal mucosal barrier. The unique feature of this case is its indolent and protracted clinical course, with a multifocal metastasis-like lesion and a distinct proliferation of spindle shaped histiocytes simulating a neoplasm. The identification of _E corrodens_ may be delayed because of its slow growth in the absence of CO₂.³ Previous trials have reported it to be resistant to clindamycin,⁸–¹⁰ metronidazole,³–⁶ and aminoglycosides,⁴–⁶ but sensitive to penicillin,⁵–⁶ ampicillin,⁶ chloramphenicol,⁴–⁶ and tetracycline.⁴–⁶ The later development of the left submandibular mass suggested that a more prolonged course of antibiotic treatment was needed to eradicate the residual microorganisms in the chronic abscess with pronounced fibrosis.

IPT is the morphological manifestation of aetiologically diverse processes with spindle cell proliferation and a variable number of inflammatory cells. There is compelling evidence that some of these fibroinflammatory masses are infection associated and often characterised by a proliferation of spindle shaped histiocytes and/or dendritic cells, in contrast to a myofibroblastic proliferation in the other IPTs, also known as IMFT.¹⁰

‘The later development of the left submandibular mass suggested that a more prolonged course of antibiotic treatment was needed to eradicate the residual microorganisms in the chronic abscess with pronounced fibrosis’

Whereas histomorphology is of limited use in differentiating neoplastic spindle cells from reactive ones, immunological studies help differentiate CD68 positive spindle shaped histiocytes from actin positive myofibroblasts, although the presence of actin positive myofibroblasts does not amount to a truly neoplastic process. Because the term IPT denotes a more reactive or reparative process than does IMFT, which confers a neoplastic diagnosis, we are of the opinion that IMFT cannot be diagnosed until the immunohistochemical identification of actin positive spindle cells or myofibroblasts. A seemingly spontaneous resolution of the left pulmonary lesion, with recurrence of multifocal non-contiguous lesions, in our case did not amount to a de facto neoplasm. Some IPTs are thought to have a bacterial aetiology but this may fail to be confirmed by culture because fastidious species are often involved. It is crucial to search for an infective origin, especially bacterial, in patients with IPT, because a lack of appropriate antibiotic treatment in bacteria associated IPT may result in clinical complications.

Take home messages

- Inflammatory pseudotumour (IPT) is a rare mass forming lesion, which is the result of an infective or reactive/reactive process (pseudotumour) in most cases, but is a true neoplasm in a few cases
- We describe an IPT, which gave the clinical impression of a metastatic neoplasm, but from which an uncommon fastidious bacillus, _Eikenella corrodens_, was cultured
- The clinical course was indolent but protracted, and the numerous lesions responded to treatment with the appropriate antibiotics
- It is extremely important that clinicians search for an infective cause of IPT (particularly because fastidious species are often involved) to ensure that appropriate treatment is given
