Possible use of phosphohexose isomerase as a preliminary to exfoliative cytology in screening for cervical carcinoma¹

GRAINGER G. MUIR

From the Department of Clinical Biochemistry, Luton and Dunstable and Bedford General Hospitals

SYNOPSIS The activities of phosphohexose isomerase and 6-phosphogluconate dehydrogenase have been studied in the vaginal fluid of women from the gynaecological departments. Women from these departments gave a very high false positive rate, though no cases of carcinoma *in situ* were not detected by estimating phosphohexose isomerase levels. It gave considerably better results in malignancy than 6-phosphogluconate dehydrogenase. It is suggested that the use of phosphohexose isomerase might be of value in screening well women during a mass cytology programme.

The success of exfoliative cytology in the diagnosis of carcinoma of the cervix has highlighted the possibility of eliminating this disease by a mass screening programme. It is agreed that a mass survey based on exfoliative cytology presents many financial and technical disadvantages.

Failure of the assays of the vaginal fluid content of beta glucuronidase (Kasdon, Homburger, Yorshis, and Fishman, 1953; Fishman, Green, Homburger, Kasdon, Nieburgs, McInnis, and Pund, 1954) and 6-phosphogluconate dehydrogenase (Bonham and Gibbs, 1962) to provide a basis for a mass screening programme has been a disappointment. Levels of both these enzymes have been raised in women with benign disease or have not been elevated in cases of carcinoma *in situ* or invasive carcinoma (Lawson, 1959; Muir, Canti, and Williams, 1964; Bell and Egerton, 1965; Lawson and Watkins, 1965). The majority of workers have been regarding enzymology as a means of replacing exfoliative cytology rather than an adjunct to it. In a mass screening programme an ability to sort out reliably those cases which might have carcinoma *in situ* from those which have not carcinoma *in situ* would relieve the cytologist of a considerable burden. The lower the number of false positive results the better, but it is more essential that no cases of carcinoma *in situ* be missed. The fact that the test is not a specific test for

carcinoma is unimportant; provided that it measures a reaction of the cervical and vaginal epithelium to abnormalities, amongst these abnormalities would be carcinoma.

Another major requirement of any mass screening technique is that it should be robust and easy to assay. Evidence in this paper suggests that the glycolytic enzyme, phosphohexose isomerase, will fill all these requirements.

Phosphohexose isomerase has been widely studied in clinical conditions. Its main use has been in the assessment of carcinoma of the breast. Bodansky (1954) followed up cases of carcinoma of the breast and found that serial estimations of the serum phosphohexose isomerase activity gave the best guide to the patient's short-term prognosis. Joplin and Jegatheesan (1962) and Jegatheesan and Joplin (1962) confirmed Bodansky's work and found that the enzyme was by far the most reliable of the serum enzymes in prognosis. Jegatheesan (1959) and Muir and Fawcett (1965) found that carcinomatous human mammary tissue had elevated enzyme levels as compared with normal breast tissue. Weber and Cantero (1957), in a study of a variety of hepatomas found that in Norikoff hepatoma the phosphohexose isomerase content was raised. Morris (1963) showed that in Morris hepatoma 5123-D and 7800, phosphohexose isomerase was not increased, but its level was not as depressed as were some of the other enzymes of glycolysis. Phosphohexose isomerase is a stable enzyme and is relatively easily estimated.

¹This work is part of an M.D. thesis submitted to the University of London.

Received for publication 21 March 1966

MATERIALS

The sources of the materials for this study were samples from women attending the gynaecological departments of the Bedford General Hospital and the Luton and Dunstable Hospital.

METHODS

The samples were collected and prepared in a similar manner to that of Bonham and Gibbs (1962). The assay of 6-phosphogluconate dehydrogenase used was that of Glock and Mclean (1953). Phosphohexose isomerase assay used was that of Bodansky (1954). The extract of vaginal fluid was diluted one in five with normal saline (0.2 ml. to 1.0) before the assay.

In this assay the micrograms of fructose-6-phosphate liberated are estimated by a resorcinol reaction and the colour developed compared with a standard curve.

CALCULATION The micrograms of fructose liberated are divided by the incubation time of 30 minutes and the molecular weight to give the μ moles liberated per minute. The milligrams of vaginal fluid in the reaction mixture is equal to milligrams per 0.1 ml. in the original dilution, since 0.2 ml. is diluted to 1.0 ml. with normal saline and then 0.5 ml. used for the reaction. Thus μ moles liberated per gram per minute

$$= \frac{\mu\text{moles per minute}}{\text{mg. per 0.1 ml.}} \times 1,000$$

RESULTS

NORMAL WOMEN The phosphohexose isomerase content of vaginal fluid was studied in 38 apparently normal women. The results are shown in Figures 1 and 2. From these figures it can be seen that 31 (80.9%) of samples gave activities of less than 3 μ moles fructose formed per minute per gram dry weight. It was felt that this level of activity should be taken as the upper limit for normal women.

In Fig. 2 the activities on these cases are compared with the activities of 6-phosphogluconate dehydrogenase.

Of the seven cases with phosphohexose isomerase levels greater than 3 μ moles per minute per gram, four samples had no detectable 6-phosphogluconate dehydrogenase activity in the samples, while two samples had 6-phosphogluconate dehydrogenase activities of less than 80 units per gram. In the remaining case the 6-phosphogluconate dehydrogenase activity was greater than 80 units per gram dry weight. Of these 38 samples only one had an elevated 6-phosphogluconate dehydrogenase; 29 had no detectable 6-phosphogluconate dehydrogenase activity.

BENIGN GYNAECOLOGICAL LESIONS One hundred and six samples were obtained from women with benign

FIG. 1. Phosphohexose isomerase activity in normal women.

FIG. 2. Phosphohexose isomerase activity in normal women.

gynaecological lesions. The results are shown in Figures 3 and 4. Twenty-eight (20.9%) of the 106 cases had levels of phosphohexose isomerase less than 3 μ moles per minute per gram. In Fig. 4 the

FIG. 4.

results are compared with 6-phosphogluconate dehydrogenase activities.

In this group 84 samples had phosphohexose isomerase levels of more than 3 μ moles per gram dry weight. Forty of these samples were associated with elevated levels of 6-phosphogluconate dehydrogenase. There were five samples with elevated 6-phosphogluconate dehydrogenase levels which did not have elevated levels of phosphohexose isomerase. The phosphohexose isomerase is very much more often elevated than the 6-phosphogluconate dehydrogenase.

If there is an elevated 6-phosphogluconate

dehydrogenase activity it is likely that phosphohexose isomerase levels will also be elevated. In Tables I and II the level of phosphohexose isomerase is compared with the overall cytological pattern. It can be seen that the presence of leucocytes or erythrocytes causes a marked increase in the level of phosphohexose isomerase, both in pre- and postmenopausal women; similar results are shown with other cytological abnormalities. In the comparison with the results with 6-phosphogluconate dehydrogenase it would appear that this enzyme is not affected to so great a degree by the presence of leucocytes or erythrocytes.

TABLE I

Cytological Pattern	RESULT IN PRE-MENOPAUSAL WOMEN					6-Phosphogluconate Dehydrogenase		
	Phosphohexose Isomerase (μ moles/min.g.)					(units per g.)		
	Nil	<3	<8	<20	>20	Nil	<80	>80
Excessive leucocytes or erythrocytes	—	7 15%	7 15%	17 38%	14 32%	13 29%	8 18%	24 53%
Increased parabasal cells	—	1	—	—	3	1	—	3
Other cytological patterns ¹	—	4	2	6	3	4	3	8
Normal patterns ²	5 54%	25 54%	10 18%	12 21%	3 7%	36 65%	11 20%	8 15%

¹The other cytological patterns include dysplasias, increased endocervical cells and low oestrogen patterns.

²Those in the normal pattern include patients with gynaecological lesions, but a normal pattern as distinct from the normal women who have neither.

TABLE II
RESULTS IN POST-MENOPAUSAL WOMEN

Cytological Pattern	Phosphohexose Isomerase (μ moles/min.g.)					6-Phosphogluconate Dehydrogenase (units per g.)		
	Nil	<3	<8	<20	>20	Nil	<80	>80

Normal patterns	—	5	2	2	—	6	2	1

VARIATIONS WITH THE MENSTRUAL CYCLE Since there were only 38 completely normal women in this series it was felt that this made too small a group to study the variations with the cycle. In order to get a larger group the normal pre-menopausal women have been grouped with those pre-menopausal women with gynaecological lesions. The menstrual cycle was divided into four-day periods and the percentage of cases with levels greater than 3 μ moles per minute per gram of vaginal debris calculated. The results are given in Figure 5. There is an expectedly high incidence of elevated phosphohexose isomerase during menstruation. There is a peak between the 12th and 16th days during the ovulatory phase, which then falls between days 16 and 20, rising again during days 20 to 24 until the end of the cycle.

Table III shows the results in post-menopausal women; both normal women and cases with benign gynaecological lesions are included. There is obviously an increase in the incidence of elevated enzyme levels in this group when compared with pre-menopausal women. The increased occurrence of elevated levels becomes more marked when they are compared with the apparently normal pre-menopausal women. In Fig. 6 the results for the two enzymes are compared; it is obvious that the phosphohexose isomerase level is more often elevated than the 6-phosphogluconate dehydrogenase.

RESULTS IN MALIGNANCY

CARCINOMA IN SITU In Table IV the results in six cases of carcinoma *in situ* are shown: estimation of

13	443	42.6

In Table VI, six cases of carcinoma of the body are shown, and seven of carcinoma of the ovary. These were all detected by estimating 6-phosphogluconate dehydrogenase, and all except two of the ovarian carcinomas, detected by phosphohexose isomerase. In general the phosphohexose isomerase is the more reliable enzyme; ovarian carcinoma is the only exception to that rule. Once again, it is apparent that the levels of the two enzymes do not correlate with each other, but it is a fair generalization that if the level of 6-phosphogluconate dehydrogenase is raised, then that of phosphohexose isomerase will also be raised.

DISCUSSION

Unlike 6-phosphogluconate dehydrogenase, phos-

phohexose isomerase is normally present in the vaginal fluid, but not usually in amounts greater than 3 μ moles per minute per gram in normal women. It is obvious that different factors regulate the level of phosphohexose isomerase in the vaginal fluid and those which regulate the 6-phosphogluconate dehydrogenase activities. In normal women they appear to be independent of each other, though if the 6-phosphogluconate dehydrogenase activity is increased, the phosphohexose isomerase is also increased. The reverse does not apply. It is increased to a considerable degree in any women with a lesion of the gynaecological tract, the incidence of activities more than 3 μ moles per minute per gram rising from 20% to about 62% in these cases. From Fig. 5 it is obvious that phosphohexose isomerase is profoundly influenced by the cytological pattern in the vagina. In pre-menopausal women with gynaecological lesions but no cytological abnormality, 46% had phosphohexose isomerase activities of more than 3 μ moles per minute per gram. If there is an excess of leucocytes or erythrocytes present, the incidence of samples with activities more than 3 μ moles per minute per gram rises to 85%. A similar change but not so large occurs with 6-phosphogluconate dehydrogenase. Phosphohexose isomerase, like 6-phosphogluconate dehydrogenase, seems to measure a reaction of the vaginal epithelium to an irritant.

Both 6-phosphogluconate dehydrogenase and phosphohexose isomerase activities in the vaginal fluid increase after the menopause. The variation with the menstrual cycle is different from that with 6-phosphogluconate dehydrogenase, in that there is a rise during the ovulatory period with a fall during days 16 to 20 and then a maintained rise during days 20 to 28. 6-Phosphogluconate dehydrogenase appears to be at its lowest level from the ovulatory period to the day immediately preceding menstruation (results to be published).

In malignancy the results with phosphohexose isomerase are very encouraging. No cases of carcin-

oma *in situ* were missed, only one of invasive carcinoma, and no case of carcinoma of the body of the uterus. The results are considerably better than those obtained with 6-phosphogluconate dehydrogenase. Estimation of phosphohexose isomerase does not appear to detect ovarian carcinoma quite so well as 6-phosphogluconate dehydrogenase. This is probably because the growth does not abut on to the vagina. This raises the interesting point as to the mechanism of the elevated level of 6-phosphogluconate dehydrogenase in ovarian carcinoma.

On first impressions such an enzyme would appear to have no potential as a diagnostic test. On the other hand there is good evidence that this enzyme has missed no cases of carcinoma *in situ*. It is unlikely that in the near future an enzyme will be found which is specific for carcinoma and sufficiently sensitive to be useful as a diagnostic test for carcinoma *in situ*. Thus at the moment it is unlikely that an enzymological test will replace vaginal and cervical cytology.

If, on the other hand, a suitable screen test is sought for carcinoma *in situ*, phosphohexose isomerase may have a place. It is an enzyme which any hospital with a standard autoanalyser could assay and it does not require any additional apparatus. If such an enzyme were used in a well women's clinic, assuming they were all apparently clinically normal, 20% of the smears would have to be inspected, and again the cytologist would have the assurance that there would probably be some pathology there. In Measday's experience (1962) the incidence of gynaecological abnormality in a well women's clinic would be between 30 and 36%. Using this figure as a basis, the number of smears which would be

eliminated can be calculated. Of 100 women attending the clinic, 36 would have some minor gynaecological abnormality. Eight per cent of these 36 would have raised enzyme levels, thus 29 smears would have to be inspected. Of the remaining 64, 20% would give raised enzyme levels, and a further 13 smears would have to be inspected. Thus in a well women's clinic 42 cases would have to be examined after the preliminary screening with the phosphohexose isomerase. The cytologist would have the confidence that of the cases he looked at, all would have a lesion; also that of the smears discarded, he would not miss a case of carcinoma *in situ*. This is a useful aspect of enzymology, and is a possibility which should be followed up on a large scale; the simplicity of automation would make a large-scale trial relatively easy.
