Electron microscopic observations on the virus particles in *Herpes simplex* encephalitis

S. ROY AND L. WOLMAN

From the Department of Neuropathology, Royal Infirmary, Sheffield

SYNOPSIS Cerebral cortex from eight fatal cases of *Herpes simplex* encephalitis has been studied by electron microscopy. The diagnosis had been based on clinical findings, necropsy evidence of bitemporal necrosis, and histological confirmation of intranuclear inclusions with a lymphocytic inflammatory response, even though virus cultures were unsuccessful. Virus particles were seen predominantly in nuclei in six of these cases, utilizing tissue which had been preserved in formalin for up to four years or had been embedded in paraffin. Although demonstration of these particles is only indicative of the herpes group and not specifically of *Herpes simplex*, electron microscopy of either biopsy or postmortem material may be a useful adjunct in making the diagnosis and can be accomplished before virological studies have been completed.

In Britain cases of epidemic and insect-transmitted encephalitis are rare. However, encephalitis caused by *Herpes simplex* virus occurs frequently in sporadic form (Grist, 1967). Similar experience has been reported from other countries (Rawls, Dyck, Klass, Greer, and Herrmann, 1966; May, Dahn, and Reuss, 1967). This disease has also been described as acute necrotizing encephalitis (Van Bogaert, Radermecker, and Devos, 1955). It is characterized by widespread inflammation of the meninges and brain associated with severe necrosis and usually presents clinically as an acute pyrexial illness of the central nervous system. In a typical case, one or both temporal lobes are most affected. If predominantly unilateral, the clinical picture may be confused with an expanding lesion of the temporal lobe, such as tumour or abscess, making it difficult to reach a clinical diagnosis.

The chance of any treatment to be beneficial will be increased by its early institution. It is, therefore, very important to diagnose the disease with certainty as quickly as possible. Several techniques may be employed for this purpose including temporal lobe biopsy, virus culture from brain, cerebrospinal fluid, pharyngeal washing and faeces, a gamma scan (Balfour, Loken, and Blaw, 1967) to demonstrate bitemporal lesions, sequential serological studies for antibodies, and the fluorescent antibody technique (Biegeleisen, Scott, and Lewis, 1959). The difficulties in finding and being certain of the

viral origin of inclusion bodies in biopsy and necropsy material and the time interval involved in culturing virus, frequently without success due to numerous factors (Wolman, 1967), led us to use the electron microscope to identify virus particles in infected material. This technique, we believe, may be of great help in reaching both an early diagnosis in life as well as in the recognition of the disease in postmortem material, especially in cases where the diagnosis remains indefinite on routine histological examination.

MATERIAL AND METHODS

Material from eight fatal cases of encephalitis was examined with the electron microscope. Of these four came from postmortem specimens of whole brains fixed in formalin for a period of one month to four years. Tissues for electron microscopy were collected from the superficial regions of the cerebral cortex, an area likely to be accessible by the biopsy needle. In one case a small amount of material was removed through burrholes from both temporal lobes after the death of the patient, permission to do a complete necropsy having been refused (case 7). In the other three cases, tissue previously embedded in paraffin blocks was used (cases 2, 3, and 6). Brief clinical and pathological details, with duration of illness and virus findings, are given in Table I. Small blocks (1 mm cube) of formalin-fixed or deparaffinized material were thoroughly washed in veronal acetate buffer before post fixation in buffered osmium tetroxide (Palade, 1952). Tissues in all cases included blocks from one or both

Received for publication 13 June 1968.

TABLE I

CLINICO-PATHOLOGICAL DATA							
Case	Sex	Age	Duration of Illness (Days)	Duration of Neurological Symptoms (Days)	Inclusion Bodies (Light Microscopy)	Virus Culture	Virus Particles (Electron Microscopy)
1	F	2	5	4	+	—	+
2	M	2	5	5	+	—	+
3	M	43	11	11	+	—	+
4	F	43	12	9	—	—	—
5	M	41	13	10	+	—	+
6	F	2½	15	13	—	—	—
7	F	10	17	14	+	—	—
8	F	1½	30	26	—	—	—

temporal lobes and at least one frontal lobe and in two also from one occipital lobe. In three cases blocks from the pons and/or midbrain were also examined. Blocks from the temporal lobes of four brains of patients who died of causes other than encephalitis were also examined. This latter group was designed to serve as a control.

After osmium fixation all the tissues were dehydrated in graded alcohol and were further processed and embedded in araldite (Glauert, 1961). Sometimes the processing time was reduced by using the method of Lynn, Martin, and Race (1966). Thin sections were cut in a Porter-Blum microtome, mounted on uncoated copper grids, stained with lead citrate (Reynolds, 1963), and examined under the AEI EM6 electron microscope using an accelerating voltage of 50 or 75 kv.

In all cases at least three blocks from each of the temporal lobes were examined and up to six blocks from other areas. No tissue from any other organ was available for examination.

RESULTS

In all these cases there was evidence of necrosis of both temporal lobes on gross and microscopic examination (Fig. 1) associated with perivascular

lymphocytic infiltration. In addition focal necrosis of other areas of the brain, including the brainstem and inflammatory infiltrates in the pia arachnoid were often present. Typical Cowdry type A intranuclear inclusions (Fig. 2) were found in several cases. Using these criteria in conjunction with the clinical findings, the cases had been diagnosed and

filed as herpes virus encephalitis. Viral studies were carried out in life or on postmortem material in four cases with negative results.

ELECTRON MICROSCOPY

Cytoplasmic preservation was very poor with marked disintegration of cell organelles, for the material used in this study came from tissues fixed in formalin for long periods or from paraffin-embedded blocks. However the nuclei could be clearly seen. As the structure of the nucleus was also altered, partly due to the viral affection and partly due to poor fixation, it was difficult to identify a particular cell type with any degree of certainty. It was, however, our impression that viral particles were present in most instances within the nuclei of nerve cells and only rarely within nuclei of astrocytes or oligodendrocytes. Nuclei containing virus particles usually showed diffuse dispersal of nuclear chromatin and/or areas of clumping. Intranuclear virus particles were found in six out of eight cases.

In all the positive cases virus particles could be seen in one or more blocks from both the temporal lobes and in two also in the frontal lobe. Virus was not found in blocks from other areas in any one of the positive cases. From one of the negative cases a total of 20 blocks, including 10 from the temporal lobes, and in the other three blocks from each of the left temporal and left frontal lobes were examined and virus particles could not be found in any. No virus particles were seen in the numerous sections examined from the control material.

The virus particles (Figs. 3 and 4) were characterized by a central electron-dense core and a surrounding capsid of similar electron density, from which the central core was separated by a less dense halo. The particles were fairly uniform in size, measuring about 90 m μ in average diameter. The central core was either spherical or slightly oval

with a diameter of 30 to 50 $m\mu$. The capsid consisted of a single membrane which measured approximately 18 $m\mu$ in thickness. Some of the viral particles did not contain any central core thus giving them an 'empty' look. The particles usually occurred in large numbers in any individual nucleus and were either loosely arranged or more closely packed (Fig. 5). Occasionally only a few particles were present, separated from each other by a wide gap. However, in an individual nucleus more than one particle was always found. In most instances the particles were present well within the nuclei but sometimes they were situated close to the nuclear membrane (Fig. 6) or actually within the layers of the membrane (Fig. 7). Figure 7 also shows a virus particle closely applied to the inner layer of the nuclear membrane. When present in this site the particles were often surrounded by a complete or incomplete second capsule and they were larger, measuring approximately 140 $m\mu$ in diameter. The nuclear membrane itself often showed reduplication (Fig. 8). Only rarely were they seen in the cytoplasm (Fig. 9).

The particles present on the nuclear membrane should be carefully differentiated from the nuclear

pores (Fig. 10) with which these may be confused (Monroe, Schidlovsky, and Chandra, 1967). The nuclear pores in favourable section also showed an outer membrane and a central dot. The overall measurement of the nuclear pores was slightly smaller than that of whole virus particles and certain other morphological differences distinguished them from the particles of viral origin. Thus the central dot of the nuclear pore was always smaller (12 to 15 $m\mu$ diameter) than the central core of viral particles and the outer membrane of nuclear pores was often indistinct and hazy in contrast to the sharp and distinct outer capsule of the virus particles. Because of tangential section the nuclear membrane was also indistinct in the region where nuclear pores were seen as round bodies. In an occasional nucleus small, uniformly electron-dense granules were present (Fig. 11).

In this study an attempt was also made to correlate the presence of intranuclear inclusions on light microscopy with the finding of virus particles by examining respectively serial thick and thin sections from the same araldite-embedded block. In some blocks where numerous intranuclear viral particles could be seen in the thin section for electron micro-

FIG. 10. Nucleus showing nuclear membrane sectioned transversely at A and tangentially at B. Nuclear pores appear as pale areas at A and as round bodies with central dot at B. $\times 32,000$.

scopy, a corresponding thick section frequently showed intranuclear inclusions on light microscopy. However, with smaller numbers of particles in thin section, light microscopic examination of thick sections usually did not show any inclusion. This observation seems to support the finding of others that intranuclear Cowdry type A inclusions are possibly of viral origin (Itabashi, Bass, and McCulloch, 1966; Chou and Cherry, 1967) and not an artifact but all viral aggregates do not present as light microscopic inclusions.

DISCUSSION

DIAGNOSTIC VALUE OF ELECTRON MICROSCOPY The technique described can be employed to make the diagnosis both in postmortem and in antemortem material, due to the ease with which the relatively large virus particles can be recognized and their stability compared with some of the surrounding cell components.

Herpes simplex virus is now well recognized as a common cause of encephalitis since it was first established as a specific entity by Smith, Lennette, and Reames (1941). In this disease involvement of the temporal lobe is a characteristic feature, first pointed out by Van Bogaert *et al* (1955) and later confirmed by other workers (Haymaker, Smith, Van Bogaert, and DeChenar, 1958; Bennett, ZuRhein, and Roberts 1962; Pierce, Portnoy,

Leeds, Morrison, and Wehrle, 1964; Adams and Jennet, 1967). At necropsy, in a typical case showing necrosis of one or both temporal lobes, perivascular lymphocytic infiltrates and Cowdry type A intranuclear inclusions, a diagnosis of *Herpes simplex* encephalitis can be made with a reasonable degree of certainty. This can be further substantiated by positive virus culture from post-mortem material. In some cases, however, a degree of uncertainty remains, especially when no intranuclear inclusions are found and no virus can be grown in culture. Examination with the electron microscope of material from these brains appears to be of great help in establishing the final diagnosis. In this study all eight cases were diagnosed as encephalitis 'possibly due to *Herpes simplex* virus' on the basis of gross and light microscopic examination of the postmortem material. In four cases, viral study attempted either in life or on postmortem material yielded negative results. However, electron microscopy demonstrated virus particles of *Herpes simplex* type in six of these, once again confirming the widely held notion that most examples of acute necrotizing encephalitis are caused by *Herpes simplex* virus. It is not possible to draw any firm conclusion about the cause of encephalitis in the two cases in which no virus particle could be found on electron microscopic examination. In one of these, the patient died 30 days after the onset of the disease and it is likely that the virus concentration of the brain was minimum or nil at the time of death.

Perhaps the more important use of electron microscopy would be its application in the diagnosis during life of clinically suspected cases. The use of antiviral agent, 5-iodo-2' deoxyuridine (idoxuridine), combined with efficient management to reduce the intracranial tension, has improved the prognosis in these otherwise hopeless cases (Breedon, Hall, and Tyler, 1966; Buckley and MacCallum, 1967; Evans, Gray, Miller, Verrier Jones, Weeks, and Wells, 1967; Bellanti, Guin, Grassi, and Olson, 1968). This antiviral agent has also been effective in treating dermal herpetic disease (MacCallum and Juel-Jensen, 1966). The continuing search for more effective antiviral agents could alter completely the poor prognosis in this disease. To get the maximum benefit from the use of such substances it is essential to institute the therapy at an early stage for which speedy and accurate recognition of the disease is imperative. Of the several diagnostic techniques mentioned earlier, none is very satisfactory for the purpose and some are time consuming. Thus it takes rather a long time (a week or more on an average) to grow the virus on tissue culture in most laboratories and only a proportion of cases yield positive results (Bennett *et al*, 1962; Drachman

and Adams, 1962; Carmon, Behar, and Beller, 1965; Miller, Hesser, and Tompkins, 1966; Itabashi *et al*, 1966). A shorter time to grow the virus has, however, been reported by MacCallum, Potter, and Edwards (1964) and Herrmann (1967). Measurement of antibody titre has to be carried out at intervals for some days to note a substantial increase before making a diagnosis and it is not very specific (Ross, Sharpe, and Ferry, 1965; Johnson, Olson, and Buescher, 1968). The fluorescent antibody technique may be valuable for quick recognition of the virus but its usefulness in the diagnosis of herpes encephalitis has not yet been established. Light microscopic examination of brain biopsy material may not always help, for it is often not possible to see all the characteristic histological changes, especially the presence of intranuclear inclusions in the small amount of material removed for biopsy examination (Gostling, 1967), although they have been reported in one case by Dodge and Cure (1956). In these circumstances it seems that electron microscopy may be a valuable adjunct, and if virus particles are present the diagnosis can be made in shorter time (two to three days) before virological studies may have been completed.

MORPHOLOGY AND DISTRIBUTION OF VIRUS PARTICLES
The structure of virus particles seen in the present study resembles those of *Herpes simplex* (Morgan, Ellison, Rose, and Moore, 1954; Stoker, Smith, and Ross, 1958; Morgan, Rose, Holden, and Jones, 1959; Epstein, 1962; Swanson, Craighead, and Reynolds, 1966; Itabashi *et al*, 1966; Chou and Cherry, 1967; Harland, Adams, and McSeveney, 1967). The fact that they are seen mostly within the nuclei is also in conformity with the observations of these authors. Particles are sometimes present within the nuclear membrane and occasionally in the cytoplasm. Morgan *et al* (1959) and Stoker *et al* (1958), in their study of cells in tissue culture infected with *Herpes simplex* virus, also found a similar distribution and postulated that the virus particles are developed in the nucleus and subsequently pass through the nuclear membrane into the cytoplasm. These authors also noted that the particles in the nuclear membrane and in the cytoplasm usually have double membranes while those in the nucleus rarely show this phenomenon. In the study of Itabashi *et al* (1966) of human material, double-walled virus particles were only found close to the nuclear membrane. In our study we failed to see any double-walled virus particles within the nucleus or in the cytoplasm but they were frequently observed within the layers of nuclear membrane. In view of the fact that nuclear membrane in infected cells often shows reduplication (Chou and

Cherry, 1967), it seems likely that the second envelope of the virus particle is usually acquired during its passage through the nuclear membrane into the cytoplasm. Occasionally the second envelope may also develop within the nucleus (Morgan *et al*, 1959). However, the absence of a double membrane in cytoplasmic virus particles in our material cannot be easily explained. The possibility is that the outer envelope is less stable and is destroyed with other cell organelles in poorly preserved material as used in our study of old formalin-fixed tissues.

The electron-dense intranuclear granules, occasionally seen in our sections (Fig. 11), are similar to those observed by Morgan *et al* (1959) in infected cells in tissue culture. Such granules were seen in cases 2 and 4 but were not found in control specimens and it seems likely that they represent either a phase in the development of virus or a change in the nucleus due to virus infection. The recent demonstration of the rapid penetration of the nucleus by viral DNA after uncoating within the cytoplasm of cells infected by *Herpes simplex* in tissue culture before replication commences (Hochberg and Becker, 1968) offers some support for the former possibility.

It is a pleasure to acknowledge the kindness of Professor W. A. J. Crane, of the Pathology Department, University of Sheffield, in allowing us facilities in his department and for the help of his technical staff.

This work was supported by a grant from the National Fund for Research into Crippling Diseases.
