From the Institute of Medical and Veterinary Science, Frome Road, Adelaide, South Australia, and the Renal Unit, The Queen Elizabeth Hospital, Woodville, South Australia

SYNOPSIS The positive identification of crystals of calcium oxalate occurring in brain and kidney after xylitol administration is described. Biochemical, histochemical, conventional light and electron microscopical methods, including selected area electron diffraction, were used to characterize the crystals.

The syndrome resulting from intravenous infusion of certain xylitol-containing solutions has been described in detail by Thomas, Edwards, Gilligan, Lawrence, and Edwards (1972a) and by Thomas, Gilligan, Edwards, and Edwards (1972b). The crystals which occurred in the brain and kidney of some of the patients in that series were positively characterized in one case which is described here.

Case Details

The patient (case 19 from the series of Thomas *et al*, 1972a) was a male, aged 58 years, who three months before admission had received a renal homotransplant following haemodialysis for chronic renal failure consequent on severe hypertension.

On 24 December 1969 he was admitted to hospital with acute pancreatitis and despite severe hypertension (210/130) the BUN at that time was 24 mg/100 ml and the serum creatinine was 1.2 mg/100 ml. The haemoglobin was 12.8 g/100 ml. The signs of acute pancreatitis resolved during controlled fluid therapy but the patient developed an epigastric mass, thought to be a 'pseudocyst of the pancreas'. In an attempt to improve his general condition he was given xylitol-containing solutions as an intravenous source of calories. Acidosis developed soon after xylitol was administered and subsequently renal

function deteriorated with rising serum creatinine (6.9 mg/100 ml), urea nitrogen (80 mg/100 ml), and uric acid (13 mg/100 ml) (Fig. 1). At this time the patient also developed 'midbrain' signs, including bilateral sixth nerve paresis, disturbances of conjugate gaze, and nystagmus. A renal biopsy was performed four days after xylitol therapy was begun and in sections rosettes and sheaves of birefringent crystals were seen in the lumen of renal tubules and within tubular cells.

Xylitol infusion had been stopped on the previous

Fig. 1 Graph showing rising serum creatinine (solid line) and falling serum bicarbonate (discontinuous line) following xylitol therapy. Haemodialysis is indicated by smaller arrows.

day after a total of 1000 ml of 25% and 500 ml of 50% solutions had been administered.

Haemodialysis was performed nine days after xylitol was first administered (Fig. 1). During this procedure the patient became shocked, with increasing abdominal pain. Intraabdominal haemorrhage was diagnosed and at laparotomy on the same day a large retroperitoneal haematoma was found behind the pancreas and extending down the left side with no obvious bleeding site. Postoperatively he became disorientated, developed neurological signs, went into respiratory failure and died on the following day.

Materials and Methods

At necropsy, about 12 hours after death, tissue was removed from the transplanted kidney and mid-brain and processed as described below.

Small portions of the solitary kidney, midbrain, and basilar artery were cut into cubes about 1 mm in diameter under 2.5% glutaraldehyde in phosphate buffer at pH 7.3 and fixed for two hours. The tissue was washed in several changes of the buffer and postfixed for four hours in 2% osmium tetroxide in the same buffer. Tissue blocks were dehydrated in graded ethanol and embedded in Epon 812 (Luft, 1961). All procedures preceding the 100% ethanol stage were carried out at 0-4°C. Thin sections for electron microscopy and electron diffraction were cut on a Porter-Blum MT2 ultramicrotome and picked up on uncoated 75/300 mesh copper grids. For conventional electron microscopy sections were stained with either saturated aqueous uranyl acetate or lead citrate (Reynolds, 1963) or both. Some sections were examined unstained, especially those used for selected area electron diffraction. A Hitachi HU 11E electron microscope was used at 75 kV, with Ilford N40 photographic plates. The microscope was calibrated for diffraction with potassium chloroplatinate crystals.

Tissue for light microscopy was fixed for three hours in 2.5% glutaraldehyde in phosphate buffer at pH 7.3 or in 10% buffered formalin. One block of kidney tissue previously fixed in glutaraldehyde was postfixed in formalin for four hours. Tissue fixed only in formalin was embedded according to conventional paraffin-embedding techniques. However, the blocks fixed in glutaraldehyde, with or without postfixation in formalin, were embedded according to the method of Meadows and Schoemaker (1970). Sections stained with haematoxylin and eosin, PAS, von Kossa stain, alizarin red, and methenamine silver were examined by both ordinary light microscopy and with crossed Nicol prisms.

Various solvents, acids, and alkalis were added

to unstained sections of kidney under a microscope and the reaction, if any, was observed. The test to identify and demonstrate calcium oxalate in tissue sections, as described by Johnson (1956, 1958), was performed.

SILICA-GEL THIN-LAYER AND GAS CHROMATOGRAPHY

The suspected calcium oxalate crystals isolated from the kidney by the method of James, Seawright, and Steele (1971) were treated with an excess of ethanol and an equal quantity of toluene was then added with a trace of concentrated sulphuric acid. The resulting turbid mixture was refluxed for two minutes and cooled. Aliquots of this were then used for the chromatography steps. Authentic calcium oxalate was treated in the same way.

THIN-LAYER CHROMATOGRAPHY

The supposed ethyl oxalate derived from the crystals was subjected to thin-layer chromatography using silica gel G (Merck) in the system petroleum ether (bp 60-80°C): ethyl acetate 19:5. The compound was visualized using the hydroxylamine-ferric chloride spray reagents described by Whittaker and Wijesundera (1952).

Upon further thin-layer chromatography the section of silica gel corresponding to the R_f value of authentic ethyl oxalate (0.58) was scraped off the plate and the compound was eluted. This was subjected to gas-liquid chromatography.

GAS-LIQUID CHROMATOGRAPHY

The suspected ethyl oxalate specimens were studied by gas chromatography using a Perkin-Elmer model 811 gas chromatograph. The column used (column 1) was a 6 ft glass column containing 0.8% neopentylglycol adipate on Gas-Chrom Q (Applied Science Laboratories). Chromatography conditions: oven temperature 70°C, injector temperature 120°C, detector temperature 125°C, and carrier flow rate 16 ml/minute. The gas chromatography was repeated using a second column (column 2) packed with a mixture of 0.6% silicone JXR and 0.6% cyclohexanedimethanol succinate (Applied Science Laboratories) on Chromosorb W.

Results

In sections stained with haematoxylin and eosin radially arranged sheaves and rosettes of crystals were seen in the lumen of the renal tubules as well as intracellularly (Fig. 2). These were morphologically the same as crystals seen in the renal biopsy during life. Some of the tubules affected were dilated and the cells atrophic. Scattered foci of lymphocytes

Fig. 3 Light micrograph of kidney using crossed Nicol prisms. Numerous birefringent crystals are present in the renal tubules. H. & E. $\times 246$.

were seen. The von Kossa stain for calcium gave a positive black reaction on the crystals. They did not stain with PAS, methenamine silver, or alizarin red. Results of solubility tests (Table I) suggested that the crystals were calcium oxalate. The Johnson test was highly suggestive of the presence of calcium oxalate, because following incineration and the addition of sulphuric acid, bubbles of carbon dioxide were produced. The resulting calcium carbonate stained with alizarin red.

Solvent	Renal Crystals	Calcium Oxalate Dihydrate (Tetragonal Form of Calcium Oxalate)
Concentrated and diluted H_2SO_4	Soluble	Soluble
Concentrated and diluted HCl	Soluble	Soluble
Glacial acetic acid	Insoluble	Insoluble
2M acetic acid	Insoluble	Insoluble
Saturated NH_4OH	Insoluble	Insoluble
4M KOH	Insoluble	Insoluble
0.5 M Li_2CO_3	Insoluble	Insoluble
Chloroform	Insoluble	Insoluble

Table I Solubility tests performed on renal crystals

Using crossed Nicol prisms the crystals were found to be strongly birefringent (Fig. 3). Some crystals were also found, by using polarized light in the wall of a midbrain blood vessel. Crystal deposition was not found in other organs.

Electron microscopy was therefore performed on kidney and brain, and although there was considerable postmortem change the cells were still intact in many areas. Small crystals with lattice planes could be found intracellularly (Fig. 4) as well as extracellularly. In Fig. 4 the occurrence of moiré fringes indicates that two flaky crystals are overlapping with their lattice planes at small angles with respect to each other.

Selected area electron diffraction (Fig. 5) on single crystals in brain and kidney gave spot diffraction patterns. The symmetry (mm), systematic absences ($h + l = 2n$ for reflections to be present), and axial ratio (0.585) of these patterns are consistent with calcium oxalate dihydrate. The space group of this tetragonal crystal is $I4/m$ and its axial ratio is 0.5944 (Donnay, 1963). The less common trihydrate is also tetragonal (space group

not reported) with a similar axial ratio (0.5961) and cannot be excluded on the basis of these data.

Even though the results of these tests strongly indicated that the crystals deposited in the kidney were calcium oxalate, chromatography provided absolute confirmation. The suspected ethyl oxalate derived from the crystals had an identical R_f value (0.58) to that of authentic ethyl oxalate (BDH) and also the ethyl oxalate prepared from authentic calcium oxalate. On gas chromatography the derivative from the renal crystals had the same retention time (3.1 min.) as authentic ethyl oxalate and also ethyl oxalate prepared from authentic calcium oxalate (Table II). The extract from the thin-layer plate had the same retention time as authentic ethyl oxalate upon gas chromatography. The results of the gas chromatography on column 2 are shown in Table II.

	Ethyl Oxalate (Authentic)	Derivative from Calcium Oxalate	Derivative from Renal Crystals
Column 1	3.1	3.1	3.1
Column 2	4.4	4.4	4.4

Discussion

On morphological characteristics the crystals appeared similar to calcium oxalate as seen in oxalosis (Peterson and Kuhn, 1965), ethylene glycol poisoning (Smith, 1951), and in the kidneys of sheep affected by excess oxalate ingestion either from feed containing *oxalis pes caprae* (Watts, 1959) or acute ammonium oxalate poisoning (James *et al*, 1971). The large amount of crystal deposited in the kidney probably accounts for the terminal renal failure in a previously well functioning homotransplant. However, scattered foci of lymphocytes seen were consistent with early graft rejection. The unusual finding of small crystals within neurons and midbrain blood vessels most probably explains the terminal neurological findings.

The above series of investigations proves beyond doubt that the crystals deposited in the brain and kidney of a patient who had received 25 and 50% xylitol infusions intravenously were calcium oxalate. The biochemical reasons and metabolic pathways for the formation of calcium oxalate in these circumstances have been discussed elsewhere by Thomas *et al* (1972a and b). This report is made because it demonstrates a multidisciplinary approach to one of the aspects of an urgent clinical problem suspected to be related to the intravenous administra-

tion of xylitol-containing solutions recently introduced into clinical use in South Australia.
