SYNOPSIS A method (Gram-MGPLG) for demonstrating micro-organisms was compared with Gram and four other known methods. Each method was tested on tissue infected with *Staphylococcus aureus*, *Pseudomonas aeruginosa* or *Neisseria gonorrhoeae*, which were then fixed in Bouin's formol saline, formol sublimate, or Van de Grift solutions. Gram-positive organisms in tissues were easily seen even at low magnification when stained by several of the methods tested.

Gram-negative organisms, however, are very difficult to locate when stained by Gram's method because tissue components and the organisms are all shades of red, whereas the Gram-MGPLG provided easier location of organisms because these are stained red while the nuclei are blue and connective tissue is green.

All methods are markedly affected by fixation; better preservation of cytological detail and improved staining reactions were produced by fixatives containing mercuric chloride.

During studies of the interaction of gonococci with fallopian-tube tissue in organ culture, it was found that Gram's technique, although staining bacteria well, failed to demonstrate cytological detail and, because it stains Gram-negative organisms and tissue elements different shades of the same colour, did not permit clear differentiation of bacteria from either the nucleus or cytoplasm, thus making interpretation of the sequence of events in the infection difficult. Rather than rely on the use of the electron microscope, we searched for a histopathological technique that would provide this information. Accordingly, five of the methods most often recommended for staining bacteria in pathological material were systematically compared with the method which we have developed in this laboratory.

Material and Methods

ORGANISMS

The bacterial strains used in this study were *Neisseria gonorrhoeae*, strain 192A, colony type 1, *Staphylococcus aureus*, strain NPH30903, and *Pseudomonas aeruginosa*, strain NPH27559.

MEDIA

All bacteria were grown at 37°C on GC agar base (Difco) supplemented with 2% v/v Isovitalex (BBL). The medium for maintaining fallopian tubes in organ culture was Eagle's minimal essential medium with Earle's salts buffered with 0.05M N-2-hydroxyethylpiperazine-N'-2 ethanesulphonic acid (HEPES, Gibco) adjusted to pH 7.45 with 1N NaOH.

FALLOPIAN TUBES IN ORGAN CULTURE

Fallopian tubes were obtained from non-pregnant premenopausal women undergoing hysterosalpingectomy for uterine fibroid tumours. The tubes were placed in glass Petri dishes in the operating room and delivered to the laboratory within 20 minutes of removal. After removal of the serosal tissues, the fallopian tube was opened by longitudinal incision and the ampullary region was cut into pieces 3-4 mm square. Three pieces were put into each organ-culture dish.

INFECTION OF FALLOPIAN-TUBE ORGAN CULTURES

Bacteria cultured for 18-22 hours were scraped from the surface of the medium with a wire loop and suspended in 0.05M HEPES. The concentration of organisms was adjusted by dilution with 0.05M HEPES so that the suspension contained approximately 2×10^6 colony-forming units per ml. The

Received for publication 6 November 1975

organ cultures were inoculated with 0.2 ml of this suspension and incubated at 37°C in airtight plastic boxes that had been flushed with 5% CO₂ in air. Three sets of fallopian-tube organ cultures were infected with *Staph. aureus*, *Ps. aeruginosa*, or *N. gonorrhoeae*.

FIXATION AND PROCESSING OF TISSUES

Twenty-four hours after inoculation the organ-culture pieces were transferred to vials containing one of four different fixatives: (i) Bouin's solution; (ii) formol saline; (iii) formol sublimate (formulae for i, ii, iii of Drury and Wallington (1967)); (iv) Van de Grift's solution (Dajani *et al.*, 1965). After 20 hours in fixative the tissues were dehydrated in graded alcohols, cleared in toluene, and embedded in paraffin wax, and microtome sections were cut 4 µm thick.

STAINING OF TISSUES

The following staining techniques were used: (1) Gram (Lillie, 1965); (2) Murray-Drew (Murray, 1919); (3) Brown-Hopps (Luna, 1968); (4) Brown-Brenn (Dajani *et al.*, 1965); (5) Gram-Twort (Drury and Wallington, 1967); (6) Gram-methyl green-pyronin—light green (Gram-MGPLG technique, developed in this laboratory during these studies).

The Gram-MGPLG technique was similar to Gram's technique (Lillie, 1965) except that counter-staining with safranin was replaced by the following steps: (1) stain 30-40 minutes in the methyl green-pyronin solution (described below); (2) rinse in distilled water; (3) stain for 10-15 seconds with 0.5% w/v light green, colour index (CI) 42095, in distilled water; (4) rinse in distilled water; (5) blot; (6) transfer directly to absolute ethyl alcohol for 5-10 sec; (7) transfer to xylene until the section is clear; (8) mount in a synthetic-resin medium. The methyl green-pyronin solution was made by combining methyl green, CI 42585, 0.15 g; pyronin, CI 45005, 0.5 g; 96% ethyl alcohol 2.5 ml; glycerin, 20 ml; and 100 ml of 0.5% w/v crystalline phenol (Analar) in distilled water. These materials were mixed with

chloroform 100 ml and allowed to stand overnight. The stain, which was the top layer, was removed carefully to avoid contamination with chloroform. The stain should be returned to the bottle and reused for 3-4 months. All dyes were obtained from Raymond A. Lamb Ltd, 6 Sunbeam Road, London NW1D 6JL.

Results

The 72 histological sections were examined to determine the colour of the nuclei, cytoplasm, collagen, and microorganisms. Table I shows which stains differentiated bacteria from cellular elements. For example, with Gram's stain, Gram-negative bacteria may be difficult to see because the tissue elements and microorganisms were various shades of red, whereas with the Brown-Hopps technique bacteria were different in colour from the surrounding tissue elements and were, therefore, more easily distinguished.

These results, however, did not take into account the effect of different fixatives on preservation of cytological detail and particularly on subsequent staining reactions. A systematic evaluation of the 24 fixative-stain combinations was therefore performed. The 72 sections, which had been coded so that the fixative and stain were unknown, were independently evaluated by two observers. Sixteen features were evaluated and graded on a scale of 0 to 4+; they were: (1) organisms seen clearly with a 10× objective; (2) organisms seen clearly with a 40× objective; (3) organisms visible outside cells; (4) organisms visible in cytoplasm; (5) organisms distinguishable from nuclear debris; (6) definition of cytological detail—clear cellular boundaries and differentiation of cellular components. Features 3 to 6 inclusive were evaluated with a 63× oil immersion objective. The scores of the two observers were averaged and the mean was expressed as the percentage of the total possible score. The results were collated to permit analysis of the effect of each fixative-stain combination on a single feature such

Staining Technique	Colour of				
	Nuclei	Cytoplasm	Collagen	Gram-positive Bacteria	Gram-negative Bacteria
Gram	dark red	red	pink-red	blue	red
Murray-Drew	blue ¹	pink	red-yellow	blue	blue
Brown-Hopps	red-brown ¹	yellow	yellow	purple	red-purple
Brown-Brenn	dark red	red	pink red	purple	red
Gram-Twort	brown-red ²	green	green	purple	brown-red
Gram-MGPLG	blue	green-blue	green	magenta	scarlet-red

as differentiation of cytological detail (table II) or on all features in aggregate (table III). These results are discussed below.

STAINING OF GRAM-POSITIVE ORGANISMS IN TISSUES

All staining techniques differentiated *Staph. aureus* from cytoplasm and collagen. Thus, the organisms were easily seen even at low magnification. With the Gram, Brown-Hopps, Brown-Brenn, Gram-Twort, and Gram-MGPLG techniques the organisms were also different in colour from the nuclei and therefore were distinguishable from nuclear debris.

Because *Staph. aureus* could be distinguished from tissues by any of the techniques, the optimal fixative-stain combination for tissues infected with staphylococci might be the one that best demonstrated cytological detail. Cytological detail was demonstrated well by the Gram-MGPLG stain with formol sublimate or Van de Grift's fixative; Gram-Twort with any fixative except Bouin's; and Brown-Hopps with formol sublimate (table II). These combinations also had high scores when other features were evaluated (table III). Thus, these fixative-stain combinations would be suitable for experimental studies with staphylococci.

STAINING OF GRAM-NEGATIVE ORGANISMS IN TISSUES

The demonstration of Gram-negative organisms was far more difficult because by four of the staining techniques the organisms were the same colour as the nuclei or cytoplasm (table I). Only by the Brown-Hopps or Gram-MGPLG technique was it possible to differentiate chromatically Gram-negative bacteria from nuclei, cytoplasm, and collagen. Because either Brown-Hopps or Gram-MGPLG with formol sublimate demonstrated organisms in tissues, both combinations would be suitable for studies on Gram-negative organisms. However, because the Gram-MGPLG was superior to the Brown-Hopps in demonstrating cytological detail (table I), it was the fixative-stain combination of choice.

To compare the Gram-MGPLG with Gram's technique, serial sections of fallopian tube infected with *N. gonorrhoeae* were stained and viewed with 10× and 63× objectives. A comparison of figs 1 and 2 illustrates the greater ease of locating bacteria stained with the Gram-MGPLG technique and demonstrates a focus of mucosal infection not seen with Gram's stain. Figs 3 and 4 illustrate that the Gram-MGPLG technique is superior to the Gram technique in preserving cytological detail and demonstrating the relationship of bacteria to host cells.

EFFECT OF FIXATIVES ON THE STAINING OF BACTERIA IN TISSUES

As shown in tables II and III, the fixatives significantly influenced the performance of the various stains. The poorest results were usually obtained when Bouin's fixative was used. Of the remaining fixatives, results depended on the stain but all gave generally good results. For instance, although formol saline was an adequate fixative for most stains, formol sublimate and Van de Grift's fixative produced greater intensity of staining and brilliance of colour with the Gram-MGPLG stain.

Discussion

Gram's stain, a time-honoured method for determining the presence of microorganisms in tissues submitted for diagnostic examination, is often used in experimental studies to investigate the interaction of microorganisms with host cells. Whereas Gram's stain may be adequate to determine the presence or

absence of microorganisms in tissues, it often fails to supply enough information. Ideally, a stain for investigating the interaction of microorganisms with host cells should permit localization of bacteria in tissue at low magnification; should stain bacteria so that they can be clearly distinguished outside cells, in the cytoplasm, and in nuclear debris; and should demonstrate the histological features of the tissues

To meet these requirements a stain would have to differentiate the colour of microorganisms from that of the nucleus and cytoplasm of host cells.

Of the five methods that we tried, several were better than Gram's stain which has the drawback of staining Gram-negative bacteria the same colour as tissue elements and of producing only poor differentiation of nuclei from cytoplasm.

The Gram-MGPLG stain, which had neither of the major defects of the Gram stain, is described in this paper. Methyl green pyronin has been used as a counterstain in the Gram's technique (Scudder and Lisa, 1931). We found this unsatisfactory because, as Scudder described, Gram-negative organisms varied from faded pink to magenta and the cytoplasm of cells was lavender to magenta. Our modification of the original methyl green-pyronin technique (Unna, 1913), when combined with subsequent staining with light green, meets the need to differentiate bacteria from host cells. The component stains, methyl green-pyronin and light green, remain stable for months and give relatively uniform results when used as described.

Although the object of these investigations was to find a fixative-stain combination that would meet the particular requirements of experimental pathological studies, the attributes of such a combination might also make it valuable in routine pathology. Although the colour differentiation of Gram-positive and Gram-negative bacteria is not quite as definitive with the Gram-MGPLG as with the Gram technique, this disadvantage seems more than outweighed by the greater ease of detecting organisms that might otherwise be missed. Thus, improved visualization of microorganisms at low magnification and better differentiation of Gram-negative bacteria within densely staining host cells provided

by the Gram-MGPLG stain may extend its value to diagnostic pathology.

We are grateful to Mr John Clark and Mr Richard Bowlby for their help with photography and to Dr David Taylor-Robinson, Dr Gerard Slavin, and Mr E. A. Wallington for their review of the manuscript.

This study was supported in part by Research Grant AI-03082 from the National Institute of Allergy and Infectious Diseases, US Public Health Service.

Dr McGee, recipient of Research Career Development Award AI-45045, participated in these studies while a Visiting Investigator from the Division of Infectious Diseases, Department of Medicine, Vanderbilt University School of Medicine, Nashville, Tennessee.
