Ethanol formed from arabinose: a rapid method for detecting *Escherichia coli*

P. J. COLOE

From the Department of Microbiology, Monash University Medical School, Prahran, Victoria, Australia 3181

SUMMARY Head-space gas-liquid chromatography showed that *Escherichia coli* are consistent in their ability to ferment arabinose with the production of ethanol. In both still and shaken cultures ethanol production is closely aligned with growth. Also ethanol production is related to inoculum size so that varying sizes of inocula may be distinguished by choosing a time of sampling early in growth. The method is suitable as a rapid test for *E. coli* and is applicable for use in detecting *E. coli* urinary tract infections.

Within the last five years many new methods have been introduced into microbiology for the rapid detection of bacteria. Techniques such as limulus lysate procedures (Jorgensen and Jones, 1975; Ross *et al.*, 1975), radiometric procedures (Buddemeyer, 1976), and microcalorimetry (Beezer *et al.*, 1974, 1975) have all been tried. However, these methods, while rapid, are relatively non-specific. Henceforth they are unsuited to rapid detection of bacteria when normal bacterial flora may be present that are similar or identical to the organisms causing the infection. In the case of urinary tract infections the method must also be able to quantify the number of organisms present so as to conform to Kass's (1957) criterion. Clearly these methods will not do that.

A method that shows promise for rapid detection and quantification, and which could be applied to urinary tract infections, is the prototype system for rapid detection and quantification of *Escherichia coli* and *Proteus* spp in urine described by Hayward *et al.* (1977a). They did extensive work on the metabolism of methionine by *Proteus* spp and concluded that the methyl mercaptan and dimethyl disulphide formed from methionine by *Proteus* spp in liquid culture could be used for the rapid detection of *Proteus* spp.

On a minor scale Hayward *et al.* (1977b) also studied fermentation of lactose and arabinose by some strains of enterobacteria. They found ethanol production from lactose in still cultures seemed to be a consistent property of *E. coli* but a variable property of other enterobacteria, whereas, in the 19 strains they tested, ethanol production from

arabinose in still culture was a consistent property. In an attempt to develop a rapid test specific for *E. coli* they established a test based on ethanol produced from lactose.

Unfortunately, ethanol produced from lactose is not specific for *E. coli*. *Klebsiella aerogenes*, for example, are equally as active. In view of this, ethanol formed from arabinose may be more useful as a rapid test for *E. coli* provided it is recognised that occasionally some other closely related enterobacteria may mimic *E. coli*. If distinction between these bacteria is required tests within the confines of the method and utilising the ability to ferment could be developed.

This paper reports a rapid method using gas-liquid chromatography for identifying and quantifying *E. coli* by detecting the ethanol produced from arabinose. The method is suitable for the rapid detection of *E. coli* and could be used to detect *E. coli* in urine. Also it could be combined with the method for rapid detection of *Proteus* spp developed by Hayward *et al.* (1977b) to give a rapid method for detecting *E. coli* and *Proteus* spp in urine.

Material and methods

Forty-nine strains of *E. coli* were studied, 39 of which were obtained from clinical material including urine (29), faeces (8), pus (1), and sputum (1). A further 10 strains were obtained from culture collections including Alfred Hospital Melbourne (6), National Collection of Type Cultures, London, Nos. NCTC 8196 and NCTC 8450 (2), and Monash University Culture Collection (2). One of the strains of

Received for publication 12 October 1977

E. coli (H19), isolated from urine, was also used for particular growth experiments. All organisms were identified by the method of Cowan and Steel (1965).

Ethanol (Townson and Mercer, Melbourne, Australia) redistilled to constant boiling point was used as a gas chromatographic standard. Whenever available biochemical-grade chemicals (British Drug Houses) were used for preparing a defined medium (Hayward *et al.*, 1977a) to which arabinose was added to replace potassium lactate. The medium was adjusted to pH 7.4 and sterilised by filtration through sintered glass. Undefined medium, culture conditions, and measurements of growth were described by Coloe and Hayward (1976).

Ethanol was detected by gas-liquid chromatography using a Perkin-Elmer 881 gas chromatograph equipped with a flame ionisation detector and a Leeds and Northrup Speedomax W chart recorder. The stainless steel column (3.66 m (12 ft) $\times$ 3.175 mm (0.125 in) outside diameter) was packed with 5% Carbowax 20 M on Chromosorb G, acid washed, DMCS treated 60/80 mesh, and the carrier gas was nitrogen at a flow rate of 21 ml/min. Temperatures used were column oven 100°C, detector 120°C, and injector 130°C.

Ethanol from bacterial cultures was identified initially by comparing the retention times of peaks with the peaks obtained after head-space analysis of standard 0.05 M ethanol solution. The identity of the product was confirmed as ethanol by mass-spectrometry.

Six millilitres of culture fluid or standard solution were added to 6 g of anhydrous K_2CO_3 in a 14 ml serum vial sealed with a rubber cap. The mixture was shaken on a rotary shaker at 160 rpm in air at 37°C for five minutes and then heated at 60°C in a water bath for five minutes, after which 500 μ l head-space gas was removed with a gas-tight syringe and injected into the gas chromatograph.

Results

ETHANOL PRODUCTION FROM ARABINOSE BY *E. COLI*

E. coli H19 was incubated unshaken for 24 hours in defined medium supplemented with 0.066 M (1% w/v) arabinose. Analysis of the headspace gas of the culture fluid showed a peak that corresponded to ethanol. Ethanol was not detected in a control culture of *E. coli* in defined medium without arabinose.

RELATIONSHIP BETWEEN ETHANOL PRODUCTION AND AERATION OF CULTURE

Since aeration increases the rate of growth of *E. coli* its influence on the rate of ethanol production was investigated. Defined medium supplemented with

Fig. 1 Time course of ethanol production by *E. coli* from shaken and still cultures in arabinose-supplemented defined medium.

0.05 M arabinose was inoculated with approximately 10^4 *E. coli* H19/ml, incubated either still or shaken, and sampled two-hourly up to 12 hours in order to perform viable counts and to determine ethanol production (Fig. 1). Ethanol was detected in the still culture early in the logarithmic phase when the viable count was low and continued to increase after the viable count had become stationary. There was a shorter lag phase in the shaken culture. In this ethanol was detected early in the logarithmic phase, starting at two hours, reaching after six hours more than 50% of the highest concentration recorded (at eight hours), and falling by about 10% by 12 hours.

RELATIONSHIP BETWEEN ETHANOL PRODUCTION AND ARABINOSE CONCENTRATION

Inocula to give 10^5 *E. coli* H19/ml were grown unshaken for 18 hours in defined medium supplemented with concentrations of arabinose ranging from 0.001 M to 0.1 M. The amount of ethanol produced increased with greater arabinose concentrations up to 0.05 M but higher concentrations did not lead to a much higher yield of ethanol (Table 1).

Table 1 Relationship between arabinose concentration and yield of ethanol

Arabinose concentration (M)	Ethanol yield (peak area in cm ²)
0.001	0
0.010	300
0.025	850
0.050	1000
0.075	1050
0.100	1100

ETHANOL PRODUCTION FROM ARABINOSE IN UNSHAKEN CULTURES OF 49 STRAINS OF *E. COLI*

Cultures of *E. coli* inoculated to give 10^6 organisms/ml in 0.05 M arabinose-supplemented defined medium and in unsupplemented defined medium as controls were incubated without shaking for eight hours, when the culture was near the middle of the logarithmic phase of growth and the different rates of growth and ethanol production between cultures were greatest. The extinction and yield of ethanol from cultures was determined (Table 2). All 49 strains yielded ethanol from the arabinose-supplemented medium. The amount of ethanol fell within a range that was less than twofold although extinction covered a wider range. Ethanol was not detected in cultures of any of the 49 strains grown in unsupplemented defined medium.

RELATIONSHIP BETWEEN INOCULUM SIZE AND AMOUNT OF ETHANOL PRODUCED

Arabinose-supplemented defined medium was inoculated with 8.0×10^5 , 4.0×10^6 , and 2.4×10^7 *E. coli* strain H19/ml. The cultures were incubated without shaking. Samples were taken at two and four hours and then hourly up to 10 hours in order to make viable counts and to measure ethanol production (Fig. 2). Ethanol was detected in the culture with the largest inoculum after only two hours and had reached more than half its final yield in four hours. Only a very small amount of ethanol was detected in the cultures with inocula of 4.0×10^6 or 8.5×10^5 at two hours, and the yields at four hours were small when compared with the culture with the largest inoculum. The amounts of ethanol formed after four hours by the cultures with a high inoculum were

Fig. 2 Time course of ethanol production from arabinose-supplemented defined medium by various inocula of *E. coli*.

clearly distinguishable from those produced by cultures with a low inoculum. At 10 hours all cultures yielded about the same amount of ethanol.

RELATIONSHIP BETWEEN MEDIUM AND ETHANOL PRODUCTION

Yeast-extract peptone water supplemented with arabinose and arabinose-supplemented defined medium were inoculated with about 10^6 *E. coli* H19/ml, incubated with shaking, and sampled at two-hourly intervals for eight hours to determine extinction and measure ethanol production. In both media significant amounts of ethanol were detected in four hours and reached a maximum by six hours.

Table 2 Range of yields of ethanol and extinction (500 nm) from eight-hour unshaken cultures of 49 strains of *E. coli* in defined medium alone or enriched with arabinose

Arabinose enrichment	Ethanol production (peak area in cm ²)		Extinction (500 nm)	
	Mean ($\pm$ SD)	Range	Mean ($\pm$ SD)	Range
Present	1008 $\pm$ 155	750-1296	0.71 $\pm$ 0.09	0.35-0.85
Absent	0	0	0.07 $\pm$ 0.05	0.03-0.08

Discussion

The results show that detection of ethanol produced from arabinose is a suitable method for rapid detection of *E. coli*. An inoculum of 10^6 *E. coli* was recognised in six hours in still culture and in less than four hours when shaken. In both still and shaken cultures ethanol production was closely aligned to growth, starting when the viable count was low and increasing throughout the logarithmic phase. In the still cultures ethanol concentration continued to rise after the onset of the stationary phase, when 20% of the total yield detected was formed. However, in the shaken culture ethanol concentration decreased after the onset of the stationary phase, indicating that the ethanol was destroyed faster than it was formed during the stationary phase in shaken culture. It was the reverse in still culture. Ethanol production from arabinose seems to be a consistent property of *E. coli* since all of the 49 strains of *E. coli* produced large amounts of ethanol after eight hours in arabinose-supplemented medium.

Because the inoculum size and the onset of production of ethanol are related varying sizes of inoculum may be distinguished by choosing a time early in growth (Fig. 2). The technique is thus well suited as a rapid test for *E. coli* in urine since it can distinguish concentrations of greater or less than 10^5 *E. coli*/ml. It is much quicker than conventional laboratory methods, easy to carry out, and relatively cheap per sample apart from the initial cost of the gas chromatograph. The method may also be combined with the rapid method for detecting *Proteus* spp (Hayward *et al.*, 1977b) to give a rapid method for detecting *E. coli* and *Proteus* spp in urine (Coloe, 1977).

I thank Dr Nancy Hayward and Professor S. Faine for their encouragement and advice and Dr A. J. C. Nicholson, Division of Chemical Physics, Commonwealth Scientific and Industrial Research Organisation, for identifying ethanol by mass spectrometry.
