From the Municipal Bacteriological Laboratory, Aurora Hospital, 00250 Helsinki 25, Finland

SUMMARY Antibodies against *Mycoplasma pneumoniae* antigen obtained by Tween-ether treatment from purified *M. pneumoniae* were measured by means of enzyme-linked immunosorbent assay (ELISA). Paired sera from 19 patients with pneumonia and from 13 patients with acute pancreatitis with a significant rise in complement fixing antibodies against *M. pneumoniae* were studied. Single sera from healthy 1-year-old children were used as controls. High levels of IgG and IgM class antibodies were seen in sera from patients with pneumonia while most patients with acute pancreatitis and all the children showed low levels of antibodies. The results indicate that ELISA using Tween-ether treated *M. pneumoniae* antigen could be used successfully in the specific laboratory diagnosis of *M. pneumoniae* infection.

The laboratory diagnosis of *Mycoplasma pneumoniae* infection is usually based on the determination of complement fixing (CF) serum antibodies and on the detection of cold agglutinins. Methods using, for example, immunofluorescence, haemagglutination, and radioimmunoprecipitation have also been reported.¹⁻³ The CF antigen contains surface glycolipids, which are shown to be the most active fraction in inducing CF antibodies, but does not contain protein.⁴⁻⁷

The surface glycolipids are, however, not unique to *M. pneumoniae*. For example, *Streptococcus MG* strain shares glycosyl diglyceride groups with *M. pneumoniae*, and similarities can be found also between *M. pneumoniae* and the cellular components of some host tissues.⁸⁻¹⁰ This raises the possibility of false positive reactions in tests using glycolipid containing antigen. The false positive reactions may be due to some heterogenic CF antibodies against some other microorganism or cellular components in tissues made free by tissue damage.^{4 11-14} Significant rises of CF serum antibodies have been reported in acute pancreatitis.^{14 15} Large amounts of antibodies against *M. pneumoniae* lipid containing antigen have also been detected in children's sera by radioimmunoprecipitation. These antibodies could be blocked efficiently *in vitro* even by lipids from carrots and parsnips, which supports the view that

the test is also measuring some non-specific antibodies.¹⁶

Recently, *M. pneumoniae* surface proteins have been isolated and partly characterised. One of these proteins has been reported to be significant to the virulence and infectivity of the *M. pneumoniae* organism.¹⁷ A method capable of measuring antibodies against such protein containing antigen might not only be more specific but also diagnostically more revealing. We have tried to achieve this by developing an enzyme immunoassay to detect different classes of antibodies against *M. pneumoniae* antigen obtained by Tween-ether treatment.

Material and methods

SERUM SPECIMENS

These included paired sera from 19 patients with a clinical diagnosis of pneumonia and with a high titre or a fourfold or greater rise in CF antibodies against *M. pneumoniae* glycolipid antigen. Also included were paired sera from 13 patients with acute pancreatitis and a significant rise in CF antibodies against *M. pneumoniae* in agreement with previous findings.^{14 15} Single sera from 30 healthy 1-year-old infants were used as controls. The CF titres in all of them were low; one-third of the group showed a titre below 8.

MYCOPLASMA ANTIGEN

M. pneumoniae was cultured according to the method of Kenny and Grayston.¹⁸ After one or two

*Present address: Division of Biomedicine, University of Tampere, Finland.

passages in PPLO broth, supplemented with 20% horse serum and 10% yeast extract, the mycoplasma was cultured on solid agar plates. The agar was then homogenised and transferred into tubes which were incubated for seven to 10 days. Bottles with PPLO broth, 16% horse serum, 2% yeast extract, thallium acetate, and glucose were inoculated with these tubes. After seven to 10 days, the suspension was filtered through gauze, and centrifuged at 13 500 rpm in a continuous-flow Sorvall rotor, and the pellet was washed with phosphate buffered saline (PBS). The washed pellet was resuspended in PBS. To this suspension Tween 80 was added to give a final concentration of 0.1% v/v. One volume of ether was added and, after mixing for 15 minutes at + 4°C, the water phase was collected. Residual ether was evaporated using N₂. The antigen was divided into small fractions and stored at -20°C. This antigen containing 2 mg of protein in stock solution (Lowry) per ml was kindly supplied by Orion Diagnostica (Helsinki, Finland).

Standard *M. pneumoniae* CF antigen (Orion Diagnostica), consisting of lipids extracted with chloroform and methanol¹⁸ from cultivated, purified organisms, was used in complement fixation.

BUFFERS

The buffer solution for diluting the antigen for enzyme immunoassay was a sodium carbonate/sodium bicarbonate buffer by Delory and King with 4.8 ml of 0.2 M Na₂CO₃ and 20.3 ml of 0.2 M NaHCO₃ and distilled water to 100 ml. The pH of this solution is 9.4. Serum and conjugate dilutions were made into PBS with 0.2% Tween 20 and 1% sheep serum.

CONJUGATES

Alkaline phosphatase bound antibodies against human IgG and IgM (Orion Diagnostica) were used as conjugates. The anti-human sera were raised in swine. Sigma 104^R alkaline phosphatase substrate was used.

THE ASSAY

The enzyme immunoassay was performed, with some modifications, according to the method of Leinikki *et al.*^{19 20} The Tween-ether treated antigen was diluted into sodium carbonate/sodium bicarbonate buffer, pH 9.4. The adsorption of the antigen on the walls of nine-well polystyrene cuvettes (Labsystems, Helsinki, Finland) was performed at room temperature overnight. During the experiments all serum incubations were done at + 37°C for 2 hours, and the serum samples were diluted 1/50 in duplicate to test the total antibody levels against the Tween-ether treated antigen. The conjugate was incubated overnight at room temperature. The final enzyme-

substrate colour reaction was measured with FP-9, a nine-channel photometer (Labsystems), and the results were given as optical density at 405 nm.

Results

To determine the most suitable working dilution for the antigen, serial dilutions were studied with a known positive and a known negative serum: samples from a patient with *M. pneumoniae* pneumonia and from a 1-year-old healthy child. A stock solution containing 2 mg of protein per ml of antigen was diluted in two-fold steps from 1/200 to 1/3200. Fresh antigen could be diluted up to 1/3200 with a clear difference between the positive and the negative serum. The optimum antigen level proved to be fairly sharply at the dilution of 1/1600, which corresponds to a protein concentration of approximately 1 µg/ml (Fig. 1). After one to two months' storage at -20°C, the antigen seemed to lose some activity, and the working dilution had to be re-evaluated.

In order to test the sensitivity of the method, a known positive and negative serum (see above) were diluted in half-logarithm steps from 10⁻¹ to 10^{-4.5}. The sera were tested with both anti-IgG and anti-IgM conjugates. In both tests the positive serum gave a slowly falling curve and was markedly different from the negative serum (Figs 2 and 3).

To compare the activities observed in various serum samples against the Tween-ether treated antigen, the specimens were all tested at the same time and the results were given as standard deviation (SD) from the mean optical density value of the control group. In the IgM test, the mean (of 30 single serum specimens from 1-year-old children) was 0.178 optical density units at 405 nm and the SD was 0.074. In the IgG test, the corresponding values were mean 0.074 and SD 0.040. There was a distinct difference between the results from patients with acute pancreatitis and *M. pneumoniae* pneumonia. Most patients with a significant rise in complement fixing antibodies against *M. pneumoniae* and with acute pancreatitis could not be regarded as having an acute mycoplasmal infection according to the ELISA results (Figs 4 and 5).

It seems likely that in the Tween 80-ether treated *M. pneumoniae* antigen proteins carry the antigenic determinants. In this study, no attempt was made to analyse and separate various protein components from *M. pneumoniae*. Further purifications are needed to elucidate the exact structure of the antigen components.

The Tween-ether treated antigen could be used in CF but had low activity. The complement fixing antigen could not, however, be used in ELISA,

Fig. 1 Serial dilutions of *M. pneumoniae* Tween-ether treated antigen tested with two known sera diluted 1/10. The positive serum is from a patient with pneumonia and with a high titre up to 4000 in complement fixing antibodies against *M. pneumoniae*. The negative serum is from a 1-year-old healthy child with a low titre in CF against *M. pneumoniae*. The ELISA results are given as the value of optical density.

Fig. 3

Figs 2 and 3 The IgM (Fig. 2) and IgG (Fig. 3) antibody levels of a known positive and negative serum (see text) diluted in half-logarithm steps from 10^{-1} to $10^{-4.5}$.

Fig. 4

Figs 4 and 5 Total IgM (Fig. 4) and IgG (Fig. 5) antibody response against *M. pneumoniae* Tween-ether treated antigen in the patient groups with acute pancreatitis and with pneumonia, and in both groups a diagnostic rise in complement fixing antibodies against *M. pneumoniae* lipid antigen. The results are given as standard deviations from the mean optical density value of 30 sera from healthy 1-year-old children tested at the same time and with the same antigen.

probably owing to weak adherence to the polystyrene cuvettes.

Discussion

A significant increase in complement fixing antibodies against the glycolipid antigen of *M. pneumoniae* has been reported in several diseases. In many of them, however, the increase is thought to be nonspecific and due probably to antigenic cross-reactions between glycolipids of *M. pneumoniae* and

Fig. 5

cellular components of damaged tissues or of other infectious agents.^{14,15} In spite of the possibility of false positive laboratory diagnoses, the tests using *M. pneumoniae* complement fixing antigen are widely used in clinical microbiology. This is due to the low sensitivity and tedious procedures of other available tests.

Recently, several applications of ELISA have been used successfully in the diagnosis of a variety of viral and bacteriological infections.¹⁹⁻²¹ These tests are both sensitive and specific. By using polystyrene

plastic sensitised with *M. pneumoniae* Tween 80-ether treated antigen we found that both IgG and IgM antibody levels reacting with this antigen could be measured.

Low levels of antibody activity against *M. pneumoniae* Tween-ether treated antigen were found in 1-year-old healthy children. This enabled us to use the standard deviation of this material as the reference and to compare other samples with the mean absorbance value of the reference group.

Patients with clinical pneumonia and a previous serodiagnosis of *M. pneumoniae* infection based on complement fixing antibodies showed mostly a rise in both IgM and IgG class antibodies between the first and second serum samples. This somewhat slow antibody formation could be explained by a theory that antibodies against the protein components of *M. pneumoniae* are first produced after a true parasitism on respiratory epithelium has taken place. Patients with acute pancreatitis and a diagnostic rise in antibodies against the glycolipids of *M. pneumoniae* mostly showed values below the level of +2 standard deviations from the control group mean even in the second serum sample. A few sera proved to have significant amounts of antibodies, even in the IgM class, which suggests the presence of a true mycoplasmal infection and would not be surprising because the sera were collected during a period of a *M. pneumoniae* epidemic. These results indicate that ELISA utilising *M. pneumoniae* Tween 80-ether treated antigen containing protein components gives a reliable mean for the diagnosis of *M. pneumoniae* infections.

The application of the IgM antibody assay offers several interesting possibilities. High levels of specific IgM antibodies would enable a diagnosis to be made from a single, early-phase serum sample. It could also be used to distinguish between primary and re-infections and in studies of the clinical differences between these two groups.
