From the Department of Haematology, The Medical School, University of Birmingham, Birmingham B15 2TJ

SUMMARY A rheological study of 32 patients with peripheral occlusive arterial disease (POAD), compared with 32 matched healthy controls, has shown no loss of erythrocyte deformability as measured by filtration methods (using initial flow rate and positive pressure instruments, polycarbonate and silver membranes, and 3 μm and 5 μm diameter pores) or by viscometry (using laser visco-diffractometric and high shear rate viscosity methods). Erythrocyte ATP concentration in POAD was also normal. Patients with POAD showed a small (4 fl) increase in mean erythrocyte volume, associated with a raised serum γ -glutamyl transpeptidase concentration, which correlated with erythrocyte filtration and viscometric measurements. Previous reports of impaired blood filterability in POAD probably reflect the effects of accompanying leucocytosis, plasma hyperfibrinogenaemia, or an increase in erythrocyte size, but not an intrinsic loss of erythrocyte deformability.

Patients with atherosclerotic peripheral occlusive arterial disease (POAD) show an increase in whole blood viscosity which is of prognostic significance and is, at least in part, caused by a raised plasma fibrinogen concentration.^{1,2} Whole blood viscosity is also influenced by erythrocyte deformability, however, and a reduction in the deformability (filterability) of POAD erythrocytes has been reported in several studies. Blood filtration through pores of 5 μm diameter is, however, influenced by factors extrinsic to the erythrocyte, such as the plasma fibrinogen concentration³ and the number of contaminating leucocytes.^{4,5} Since POAD patients may show hyperfibrinogenaemia or a leucocytosis as part of the haematological stress syndrome,^{6,7} previous reports of either reduced whole blood filtration,⁸⁻¹¹ reduced filtration of erythrocytes suspended in autologous plasma,^{12,13} and reduced filtration of washed erythrocytes contaminated with leucocytes,¹⁴ may reflect these extra-erythrocytic factors. This is supported by the failure to show any persisting loss of erythrocyte filterability when POAD erythrocytes are suspended in normal plasma¹⁵ or when erythrocyte filtration is corrected mathematically for contaminating leucocytes using regression lines.^{4,16}

Although erythrocyte filtration is sensitive to leucocyte contamination,⁵ regression line correction methods^{4,16} may introduce other errors and reduce test sensitivity to alterations in erythrocyte deformability. There has been no previous report of the filterability of leucocyte free, washed POAD erythrocytes, and we have therefore studied the erythrocyte deformability of 32 POAD patients and 32 matched controls using initial flow rate (Hemorheometre) and positive pressure (Erythrometre) filtration methods. Viscometric measurements of erythrocyte deformability were also made using Contraves LS30 and laser diffractometric (Ektacytometer) instruments. Since a reduced erythrocyte ATP concentration has been reported in POAD,¹⁷ and has been claimed to be a cause of decreased erythrocyte deformability, we have also studied erythrocyte ATP in a cohort of patients and healthy controls.

Patients and methods

PATIENTS

The 32 patients with POAD (age range 50-77 years, 25 male) were studied as outpatients or on admission for angiography. All had atherosclerotic, non-diabetic, large vessel disease, confirmed by angiography and by reduced or absent peripheral pulses. All were normotensive and there was no biochemi-

Table 1 Comparison of mean (SEM) haematological and biochemical values for 32 patients with peripheral occlusive arterial disease (POAD) and 32 matched controls

	POAD	Significance <i>p</i>	Controls

*Mann-Whitney U test for 20 patients and 21 controls.

cal evidence of renal insufficiency. Rest pain was present in three but none had gangrene; the mean (range) claudication distance was 250 (45–1500) metres. The 32 healthy controls (age range 44–77 years, 25 male) were closely matched (Table 1) for age and smoking habit and had no clinical evidence of vascular disease; biochemical tests of liver and renal function were normal. POAD smokers averaged 14 cigarettes a day and control smokers 20 a day.

METHODS

Blood samples for all rheological tests were taken from an antecubital vein into lithium heparin (15 IU/ml blood; Sterilin Ltd, Feltham, Middlesex) and analysed within 4 h.⁵ Erythrocyte filterability was measured using erythrocytes that were leucocyte and platelet free as prepared by the Imugard IG500 cotton wool prefiltration technique followed by two washes in phosphate buffered saline (PBS) of pH 7.4 and osmolality 297 mmol/kg.^{18–19} More than 99.5% of leucocytes and platelets (as assessed by Neubauer counting chamber) were consistently removed. Initial flow rate filtration²⁰ was measured at ambient temperature using the Hemorheometre SPO2 (Bell System [Telephones] Ltd, Barnet) as previously described.²¹ Disposable polycarbonate membranes of 5 μ m pore diameter, taken from a single batch (Nuclepore Corporation, Pleasanton, California, USA; batch 54 FOC 138), and reusable silver Selas membranes of nominal 5 μ m (batch 5872) and 3 μ m (batch 013) pore diameter (Flotronics, Spring House, Pennsylvania 19477, USA), were used. The silver membranes were cleaned and reused after each erythrocyte filtration as previously described²¹ but were ultrasonicated for a total of 10 s in 20 ml of 1% wt/vol sodium dodecyl sulphate solution. Hemorheometre results were expressed as an index of filtration (IF) after correction for haematocrit²⁰ as measured by Coulter S counter (Coulter Electronics Ltd, Luton). IF was measured only once using the silver membrane, but two measurements were made

using (different) polycarbonate membranes and the mean taken. When the latter two values were not within 10% (about 1/5 of all tests) a third membrane was used and the mean of the closest two readings was then taken.

Positive pressure erythrocyte filtration was measured at ambient temperature, again after passage of blood through Imugard IG500 cotton wool, using the Erythrometre II (SEFAM, Nancy, France) at a standard washed erythrocyte count (Coulter ZF counter) of $0.5 \times 10^{12}/l$, a flow rate of 5 ml/min, and 5 μ m pore diameter Nuclepore filters. Results were expressed as a filtration pressure index (I) by dividing the final pressure at 3 min by that for buffer alone at 1 min.²² Only one measurement of I was made on each blood sample.

Laser visco-diffractometry measurements on whole blood were made at ambient temperature using the Ektacytometer (Technicon International Division, Saint Denis, France) as previously described.^{23–24} The parameters measured included the elongation index (EI) for whole blood, at a shear stress of 16 Pa, and the osmotic deformability profile,²⁵ or Osmoscan plot, in which erythrocyte elongation is measured in a continuously increasing osmotic gradient (100–450 mmol/kg). The maximum elongation index in the latter (EI max) was recorded.

Red cell viscosity was measured at 25°C using erythrocytes that were washed three times in PBS (but without contact with Imugard IG500 cotton wool), resuspended in PBS at $2.0 \times 10^{12}/l$, and sheared at a rate of 241 per second in a Contraves LS30 2T–8T viscometer (Contraves Industrial Products Ltd, Ruislip) as previously described.²⁶ Plasma viscosity was measured at 25°C using a Coulter-Harkness capillary viscometer (Coulter Electronics Ltd).

Erythrocyte ATP concentration was measured in 20 patients and 21 controls by ultraviolet spectrophotometry (Pye Unicam SP8-100, Cambridge) using a Test-Combination ATP kit (Boehringer Mannheim GmbH Diagnostica) based on the

method of Bücher.²⁷ γ -glutamyl transpeptidase was assayed at 25°C using a Merck test kit (EM Diagnostics, Poole) and a Kone CD analyser (Kone Instruments, Stockport). Serum biochemical profile was measured by SMA 12/60 (Technicon Instruments, Basingstoke). Erythrocyte mean cell volume (MCV) was measured by a Coulter S counter. Quality assurance was determined for the Hemorheometre and Erythrometre methods by daily measurements of the flow time of a sterile aliquot of dextran 70 in 0.9% sodium chloride (Fisons Ltd, Loughborough) through the 5 μ m pore polycarbonate and silver membranes, as previously described.²¹

Statistical significance was determined by the Mann-Whitney U test (two tail) and by correlation coefficient.

Results

The 32 patients were closely matched for age, sex, and smoking habit, and fortuitously for leucocyte count, with the 32 healthy controls (Table 1). The patients' erythrocytes showed a significantly higher MCV, presumed to be a consequence of higher alcohol intake since nine patients, but only two controls, had serum γ -glutamyl transpeptidase concentrations above the upper limit of the reference range (6–25 U/ml); the mean γ -glutamyl transpeptidase concentration of the patients was significantly higher than that of the controls (Table 1). The patients also showed significantly higher plasma viscosities than the controls, but the mean erythrocyte ATP concentration (reference range 375–631 μ mol/l) was not significantly different.

Quality assurance was satisfactory for the 5 μ m filtration methods. Coefficients of variation (CV) were calculated from the daily flow times of dextran

70 for each of the 45 working days of the study. The Hemorheometre 45-day CVs were 4.8% for 5 μ m polycarbonate membranes and 6.6% for 5 μ m silver membranes. A 45-day CV of 12.0% was obtained for the Erythrometre using 5 μ m polycarbonate membranes.

None of the tests of erythrocyte filterability showed a significant difference between patients and controls (Table 2). The IF values for 5 μ m pore polycarbonate and silver membranes closely correlated with one another within both the 32 patients ($r = 0.700$, $p < 0.001$) and the 32 controls ($r = 0.618$, $p < 0.001$). Thus despite the difference between the straight channel pores of the polycarbonate membranes and the tortuous channel pores of the sintered silver membranes, the indices of filterability were similar. There was no significant correlation between the initial flow rate IF values, using 5 μ m pore polycarbonate membranes, and the I values obtained after positive pressure filtration for 3 min using similar membranes; these two filtration indices therefore seem to measure different rheological parameters.

A larger group of 99 subjects (40 POAD patients and 59 healthy controls), from which the 32 matched pairs were taken, was used to assess the relation between MCV and IF values. MCV correlated weakly but significantly with IF for both 5 μ m pore polycarbonate ($r = 0.213$, $p < 0.05$) and 5 μ m pore silver ($r = 0.210$, $p < 0.05$) membranes; MCV did not correlate significantly with I, however ($r = 0.091$). Within the smaller number of 32 matched POAD patients, and within the 32 controls, there was no significant correlation between MCV and any of the above filtration measurements.

Measurement of red cell viscosity at high shear rate did not show any significant difference between POAD patients and controls, but laser visco-

Table 2 Comparison of mean (SEM) rheological values for 32 patients with peripheral occlusive arterial disease (POAD) and 32 matched controls

	POAD	Significance <i>p</i>	Controls
Initial flow rate filtration (IF)			
Polycarbonate 5 μ m	13.8 (0.2)	NS	13.5 (0.9)
Silver 5 μ m	11.7 (0.2)	NS	11.3 (0.2)
*Silver 3 μ m	30.9 (1.3)	NS	33.1 (2.3)

Red cell viscosity (mPas)	1.66 (0.01)	NS	1.63 (0.02)
Laser visco-diffractometry			
EI	0.55 (0.01)	<0.02	0.53 (0.01)
EI _{max}	0.58 (0.01)	<0.05	0.57 (0.01)

*Mann-Whitney U test for 13 patients and 12 controls.

IF = index of filtration.

I = filtration pressure index.

EI = elongation index.

NS = not significant.

diffraction showed apparently increased elongability (EI and EI_{max}) for POAD erythrocytes (Table 2). This is in part an instrument artefact since EI correlated with MCV within the 32 patients ($r = 0.352$, $p < 0.05$) and within the 32 controls ($r = 0.552$, $p < 0.01$); analysis of the diffraction image in the Ektacytometer is not compensated for cell size. Apart from EI , the Ektacytometer Osmoscan plots, which showed the relation between erythrocyte elongation index and osmolality, were similar between patients and controls.

Discussion

In this study particular care was taken to match POAD patients with healthy controls and to use a range of rheological methods that measure different aspects of erythrocyte deformability. Our filtration methods included an initial flow rate gravity system (Hemorheometre), with a calculated maximum shear stress of 60 Pa, and a positive pressure filtration system (Erythrometre), with a shear stress of 37 Pa for normal erythrocytes. With the exception of Ehrly and Köhler,¹² who used 8 μ m pore diameter Millipore filters, previous filtration studies in POAD have almost exclusively employed 5 μ m pore disposable polycarbonate (Nuclepore) membranes. In addition to these membranes we studied reusable silver membranes of both 5 μ m and 3 μ m nominal pore diameter since they may have differing sensitivity in the detection of impaired erythrocyte deformability.²¹ A quality assurance programme was also used throughout the study and this showed satisfactory day to day instrument and membrane reproducibility.

Our filtration measurements were performed on erythrocytes that had been passed through Imugard IG500 cotton wool and then washed twice in PBS. This technique removes >99.5% of leucocytes and platelets, as well as plasma proteins, but does not cause selective removal of erythrocyte sub-populations such as microcytes, macrocytes, reticulocytes, irreversibly sickled cells, or erythrocytes containing inclusion bodies.¹⁸ Although we have not yet been able to show that the cotton wool does trap any erythrocyte sub-populations, it is theoretically possible that less deformable POAD erythrocytes could have been selectively removed. Additional (viscometric) methods for measuring erythrocyte deformability, without cotton wool contact, were therefore studied in parallel.

None of the rheological methods used showed any loss of deformability of POAD erythrocytes and we assume that previous studies showing loss of erythrocyte filterability were influenced by contamination of the test erythrocyte suspensions with leucocytes

Bareford, Lucas, Caldwell, Stone, Baar, Stuart or plasma proteins or both. We have also been unable to confirm a widely quoted report of reduced erythrocyte ATP concentration in POAD, which was based on a study of four patients and four unmatched controls.¹⁷ In a separate study,²⁸ we have shown that POAD erythrocytes have a similar reduction in filterability to that of normal erythrocytes when exposed to an in vitro metabolic stress (low pH, low pO_2 , and hyperosmolality) designed to simulate the effects of local ischaemia in poorly perfused tissues. The above studies, therefore, suggest that POAD erythrocytes taken from the antecubital fossa do not have a demonstrable loss of deformability within the limits of sensitivity of current techniques.

In rheological studies the patient and control groups should be carefully matched for age, which influences both plasma fibrinogen concentration,²⁹ and erythrocyte MCV.^{30,31} Matching for smoking habit is also important since smoking increases fibrinogen concentration,²⁹ the MCV,^{30,31} and also the leucocyte count.³²⁻³⁴ Alcohol intake is a further cause of macrocytosis,^{30,31} and since erythrocyte deformability measurements may be influenced by MCV values, both outside the normal range³⁵ and to a much lesser extent within it, the effect of alcohol intake on MCV should be checked in future rheological studies.

We are indebted to the United Birmingham Hospitals Endowment Fund Medical Research Committee and the University of Birmingham Scientific Projects Committee for financial support, to Miss CP Hopwood for ATP measurements, to Technicon International Division for making available an Ektacytometer, and to Mr MH Simms for allowing access to patients attending the vascular clinic.
