Iron state in alpha and beta thalassaemia trait

JM WHITE, R RICHARDS, G JELENSKI, MARGARET BYRNE, M ALI

From the Department of Haematology, Corniche Hospital, Abu Dhabi, United Arab Emirates

SUMMARY The iron state was examined in two groups of pregnant women who were carriers of α and β thalassaemia genes. In both groups the haematological expression of the disease—namely, haemoglobin and mean cell haemoglobin concentrations—was nearly identical. In patients with α thalassaemia the ferritin concentrations and percentage of ferritin deficiency was the same as in normal pregnant patients, whereas in those with β thalassaemia the ferritin concentrations were usually much higher and iron deficiency four times less common. This variance appears to be explained by different degrees of extravascular or intravascular haemolysis between the two thalassaemias as assessed by the activities of serum α hydroxybutyrate dehydrogenase.

In 1984 Pardini *et al* reported that in patients with α thalassaemia concentrations of ferritin were similar to those of normal subjects, and were significantly lower than those associated with β thalassaemia, but no explanation was given.¹ We made a similar observation indirectly during a larger study on the haematological changes in pregnancy in over 2000 mixed ethnic patients with the thalassaemia trait (α and β).² By 36 weeks' gestation patients with α thalassaemia showed the same incidence of iron deficiency as normal mothers (15–20%), but in those with β thalassaemia iron deficiency was uncommon (4%). Moreover, the difference in routine ferritin concentrations between the two became so obvious that the association of thalassaemic indices and a "high" ferritin concentration (> 40 ng/100 ml) was almost diagnostic of β thalassaemia, but if the concentration was normal or low (< 15 ng/100 ml) α thalassaemia was suspected. We had not, however, taken into account any differences in the cellular expression between the two thalassaemias—namely, haemoglobin concentrations and mean cell haemoglobin values—or made allowance for the differences in age or parity.

We therefore re-examined the problem in two selected groups of patients in which these factors, especially haematological expression, were comparable or identical. At the same time the degree of extravascular and intravascular haemolysis was assessed by measuring the concentrations of serum α hydroxybutyrate dehydrogenase.

Subjects and methods

The subjects were peninsular Arab women (from Yemen, United Arab Emirates, and Oman) who were carriers of either α (No 42) or β (No 23) thalassaemia and in the 36–40 week of pregnancy. All were para II + I and between the ages of 20 and 25 years. They were receiving normal antenatal care with supplements of iron (100 mg three times daily) and folate. The timing of pregnancy was chosen to provide the period of highest incidence of iron deficiency. The number of pregnancies and age of each patient was included to provide some equivalence of iron loss (years of menstruation plus three pregnancies).

A control group of Arabic women over 36 weeks' pregnant who had normal haemoglobin concentrations for the period of gestation, a normal mean cell haemoglobin value, and no other clinical complications was also studied.

The routine haematological variables were measured on a Coulter model S. The performance of the laboratory was monitored monthly by the NEQAS United Kingdom quality assurance programme, and in 1983–84 the deviation index was 0.5 (good). Haemoglobin A₂ concentrations were measured by polydexide chromatography (normal range (SEM) 1.8–3.2% (0.15%)).³ Serum ferritin concentrations were measured by radioimmunoassay using commercial kits (Amersham UK). Serum α -hydroxybutyrate dehydrogenase was measured with the Boehringer commercial kit.

DIAGNOSIS OF α AND β THALASSAEMIA

The diagnosis of α and β thalassaemia was made using the criteria described previously²—namely, the patients were screened by discriminant

Table 1 DNA analysis of α gene complex in patients with α thalassaemia*

No of patients	Ethnic group	Haemoglobin g/l	Red cell count ($\times 10^{12}/l$)	Mean cell haemoglobin (pg)	Mean cell volume (pl)	Hb A ₂ (%)	Ferritin ng/100 ml	Discriminant function	Genotype
1	Yemen	115	5.14	22	67	3.3	13.2	+1	$-\alpha/-\alpha$
6	Oman	105	5.01	22	64	3.2	6.0	+5	$-\alpha/-\alpha$
10	United Arab Emirates	108	4.68	22	72	3.1	18.4	+9.9	$-\alpha/-\alpha$
12	United Arab Emirates	107	4.99	21	67	2.9	40.8	+5.1	$-\alpha/-\alpha$
18	Oman	91	4.7	19	59	3.6	87.0	+5.4	$-\alpha/-\alpha$
3	Yemen	111	5.03	22	67	2.7	44.5	+3.1	$-\alpha/\alpha\alpha$
7	United Arab Emirates	107	5.8	21	67	3.8	56.5	+5.1	$-\alpha/\alpha\alpha$

*Data were extracted from the larger study.⁵ In some of these patients the ferritin and Hb A₂ concentrations are higher than those of the patients reported in the present study. This was probably due to technical variation.

Table 2 Haematological variables of patients with α or β thalassaemia

	Normal patients (n = 50)		Patients with α thalassaemia (n = 42)		Patients with β thalassaemia (n = 23)	
	Range	Mean	Range	Mean	Range	Mean
Haemoglobin (g/l)	116–131	123	84–125	107	87–111	102
Red cell count $\times 10^{12}/l$	3.8–4.3	3.95	4.9–6.1	5.7	5.1–6.3	5.8
Mean cell volume (fl)	80–92	87	63–70	65	62–70	64
Mean cell haemoglobin (pg)	28–32	30	18–22	21	18–22	20.2
Discriminant function	+7 to +20	+13.5	+3 to -1.6	+0.6	+1.3 to -2.0	-1.2
Hb A ₂ (%)	2.1–2.6	2.3	1.7–2.3	2.1	4.8–6.3	5.2

Fig. 1 Geometric means and ranges of serum ferritin concentrations in: normal non-thalassaemic patients; patients with α thalassaemia; and patients with β thalassaemia.

function analysis of the haematological variables using the formula: (mean cell volume – red cell count – (5 $\times$ haemoglobin concentration – 3.4)),⁴ and if the function indicated a thalassaemic pattern they were divided into α and β thalassaemia by measuring the HbA₂ concentrations.

We were aware of the danger of making a diagnosis of α thalassaemia without biosynthetic data. The validity of this selection procedure has, however, been supported by DNA analysis of the α globin gene complex of seven patients with mean cell haemoglobin values of between 18 and 25 pg, selected by discriminant function analysis.⁵ Five of these patients were homozygous for the 3.7 deletion and two were heterozygous (Table 1). Once the patient was diagnosed as a carrier of thalassaemia the serum ferritin concentration and α hydroxybutyrate dehydrogenase activity were measured on fresh repeat samples by an independent observer.

Results

Table 2 gives the range and the geometric means of the haematological variables of the two groups of patients studied compared with those of normal patients. There was little difference in the haematological expression of the thalassaemias with the exception of the mean cell haemoglobin value, which although marginally lower in the β thalassaemia group, was still not significant.

Fig. 2 Geometric means and ranges of serum hydroxybutyrate dehydrogenase (α -HBD) concentrations in: normal control patients; patients with α thalassaemia; and patients with β thalassaemia.

Fig. 1 shows the geometric means and ranges of the serum ferritin concentration associated with the two groups of patients with thalassaemia and the normal group. There was no difference between the mean (SEM) concentration associated with β thalassaemia (14.1 (3.8) ng/ml) and normal (13.6 (3.2) ng/ml), but the mean value associated with the β thalassaemia group was much higher (42.8 (6.4) ng/ml). In addition, whereas the incidence of iron deficiency ferritin (< 10 ng/ml) in the α thalassaemia group (16%) was roughly the same as that found in the normal pregnant group (14%), it was only 3% in the β thalassaemia group.

SERUM HYDROXYBUTYRATE DEHYDROGENASE ACTIVITIES

Fig. 2 shows the activities of serum α hydroxybutyrate dehydrogenase. The mean (SEM) value for normal controls was 176 (15) IU/l; for the α thalassaemia group 221 (36) IU/l; and for the β thalassaemia group 363 (52) IU/l. The significance of difference between

Fig. 3 Comparison between development of iron deficiency in 738 patients diagnosed as having α and β thalassaemia during gestation. Unshaded curve indicates patients who were iron replete at 20 weeks and shaded area indicates those who were found to be iron deficient at > 36 weeks. (The relative incidence of ferritin deficiency between α and β is 4:1.) This figure also shows that the development of iron deficiency has little if any effect on haemoglobin A_2 concentrations. If this were the case there would be a sharp left shift in the haemoglobin A_2 distribution of both α and β thalassaemic patients.

patients with α thalassaemia and normal patients was 0.15, but between those with β thalassaemia and normal patients 0.001, and between those with β thalassaemia and α thalassaemia 0.01.

Discussion

These data confirm early findings² that there is a noticeable difference in ferritin concentrations, and presumably iron state, between carriers of α thalassaemia and β thalassaemia and support the findings of Pardini *et al.*¹ The problem is simply illustrated in Fig. 3, which is taken from data from our earlier study.² This compares the number of patients diagnosed as having α or β thalassaemia in early pregnancy, at which stage they had normal ferritin concentrations, with the number of those who subsequently became deficient in iron during the course of pregnancy. The development of iron deficiency was largely confined to the α thalassaemia group.

To determine the cause for this variance we attempted in this present study to eliminate possible and obvious factors—namely, gestational variation, ethnic variation, and differences in cellular expression between the thalassaemias. With regard to the

Iron state in α and β thalassaemia trait

difference in cellular expression, although our groups were comparable, they were not exactly the same as it was difficult to find large numbers of patients with α thalassaemia with mean cell haemoglobin values of 18–22 pg. Nevertheless, although accepting that β thalassaemia is marginally more severe than α thalassaemia, the difference is not likely to explain the noticeable difference in the ferritin concentrations. We suggest, therefore, that the difference in iron state reflects the different degrees of dyserythropoiesis or intravascular haemolysis. We are aware that the α hydroxybutyrate dehydrogenase activity is only a guide to intravascular haemolysis and suggest that the study should be repeated using a more sensitive marker. It is, however, a simple and readily available test and indicates that alterations in the activities of α hydroxybutyrate dehydrogenase may in individual patients be of value in monitoring changes in the disease.

Finally, the common, or rather “normal,” incidence of iron deficiency in women with α thalassaemia might result in confusion as to the correct diagnosis. Alternatively, once a patient has been diagnosed as having α thalassaemia, especially women, it must be assumed that they will develop iron deficiency at the

same rate as normal patients. Unfortunately, hypochromia will not be a guide.

We thank the nursing staff of the Corniche Hospital and Mrs Penny Stott and Mrs Val Rivers for their clerical help. We also thank Dr M Pippard for his helpful and critical comments.
