Prevalence of human herpesvirus 6 in lung tissue from children with pneumonitis

J A Hammerling, R S Lambrecht, K S Kehl, D R Carrigan

Abstract

Aims/background—Human herpesvirus type 6 (HHV-6) is the aetiological agent of exanthem subitum, and has also been linked with a variety of other diseases. The aim of this study was to investigate the role of HHV-6 in pneumonitis in children. **Methods**—Formalin fixed, paraffin wax embedded lung tissue from 33 children (age range two months to 16 years) who died with pneumonitis was subjected to immunohistochemical staining for HHV-6 using an avidin-biotin method.

Results—Active HHV-6 infection was demonstrated in four children: a bone marrow transplant recipient with concomitant adenovirus infection, a patient with hepatitis of unknown aetiology, a patient with congenital anomalies, and a patient with congenital immunodeficiency.

Conclusion—Accurate localisation of HHV-6 is possible in postmortem lung tissue. HHV-6 either alone or in combination with other pathogens may play a role in the development of pneumonitis.

(J Clin Pathol 1996;49:802-804)

Keywords: human herpesvirus 6, viral pneumonitis, children.

Human herpesvirus 6 (HHV-6) is a recently discovered virus that, on the basis of serological evidence, seems to infect most children by the age of three years.¹ However, the clinical manifestations of primary HHV-6 infection and reactivation have not been well defined, except for the report by Yamanishi *et al*² that identified HHV-6 as the agent of exanthem subitum and a report by Hall *et al*³ on complications and reactivation of HHV-6 in children. Previous work from Carrigan *et al*^{4,5} has established HHV-6 as a cause of interstitial pneumonitis in bone marrow transplant recipients and patients with AIDS.

Very few data exist regarding the role of HHV-6 infection in paediatric interstitial pneumonitis. We therefore investigated the role of HHV-6 in the development of pneumonitis in both immunocompetent and immunocompromised paediatric patients ranging in age from two months to 16 years.

Methods

An average of eight paraffin wax blocks of lung tissue prepared at necropsy from each of 33 paediatric patients with any type of pneumonitis as a primary or contributing cause of death

were retrieved from the archives of the Department of Pathology, Children's Hospital of Wisconsin. All patients had died between 1991 and 1994.

Cases of both diagnosed and idiopathic pneumonitis were included. Cases were also subdivided according to age: less than two years for presumed primary infections and more than two years for presumed late primary or reactivation disease. One of the cases studied (case 4; tables 2 and 3) has been described in detail previously,⁶ but was independently selected by the criteria used here.

DETECTION OF HHV-6

Immunohistochemical staining for the identification of HHV-6 infected cells based on an avidin-biotin system (Vector Laboratories, Burlingame, California, USA) has been described in detail by Russler *et al*.⁷ The primary antibody used was a rabbit hyperimmune serum specific for cells actively infected with HHV-6. The alkaline phosphatase enzyme was used with a Vector Red reaction substrate and haematoxylin counterstain.

A negative control of each section was run in parallel with pre-immune serum from the same rabbit used for production of the HHV-6 specific antiserum. A positive control consisted of lung tissue from a young male bone marrow transplant recipient who died of fulminant HHV-6 pneumonitis.⁴ Internal controls of normal lung tissue, cytomegalovirus (CMV) infected lung tissue and adenovirus infected lung tissue, from patients who had these viruses isolated from necropsy lung tissue, were used as negative controls and proof against cross-reactivity of the antibody. Lack of cross-reactivity of the rabbit antiserum has also been shown previously.⁶

HHV-6 infected cells were counted and the number of infected cells per cm² was calculated. Measurement of the size of the tissue sections in cm² excluded regions that were acellular or necrotic.

Determination of HHV-6 infected cell types was accomplished by double immunohistochemical staining, which has been described previously.⁸ Briefly, the rabbit antiserum was used first with an alkaline phosphatase/Vector Red substrate (fig 1). Then, cell type specific monoclonal antibodies were used with a horseradish peroxidase/Vector SG substrate. The cell type specific primary antibodies used were: mouse anti-human macrophage (CD68); mouse anti-human epithelial membrane antigen (EMA); and mouse anti-human T cell

Results

Population characteristics of the 33 patients studied are shown in table 1. All had lung disease at the time of death, except for the internal, blind negative control patient. HHV-6 serostatus was unknown for all patients. Of the patients, 22 died with no known aetiology for their pneumonitis, while 11 deaths with known aetiologies consisted of varied bacterial, viral, and fungal pathogens. Respiratory failure was the cause of death in 12 patients, and 21 had pneumonitis as a contributing, but not the primary, cause of death.

The immunohistochemical staining procedure used in this study permitted easy diagnosis and quantitation of HHV-6 infected cells in routinely processed postmortem lung tissues. It is important to note that at the time of necropsy, no specimens were tested for the presence of active HHV-6 infection by culture. Four (12%) patients had had active HHV-6 infection, with levels varying from 29 to 579 cells per cm^2 (table 2). Identification of HHV-6 infected cell types resulted in positive cytoplasmic staining in both lymphocytes and macro-

phages, on the basis of their reactivity with the appropriate monoclonal antibody. The numbers of lymphocytes and macrophages infected were roughly equal, with no epithelial cell involvement detected.

The cause of death in two of the four patients infected with HHV-6 was identified as respiratory failure in cases 1 and 4, as hepatic necrosis in case 2, and as systemic adenovirus infection in case 3.

Two of the four patients with HHV-6 infection were known to be immunocompromised, either because of bone marrow transplantation or congenital immune deficiency. The clinical features of the patients are presented in table 3. Potential pathogens identified at the time of death are listed in table 4.

Discussion

This study demonstrates that some cases of idiopathic interstitial pneumonitis are probably caused by active HHV-6 infection. Comparing the rate of positive HHV-6 cases ($n = 4$) with those of CMV ($n = 4$), currently one of the most common causes of interstitial pneumonitis in the immunocompromised patient, we found equal rates of positivity (table 4).

Two of the four patients infected with HHV-6 were known to be immunocompromised. The remaining "competent" patients had no known immunodeficiencies, but could have been functionally compromised by nutritional status or other factors. Although data are limited, this study suggests that HHV-6 infection has no preference for host immune state in the paediatric patient. The otherwise healthy child can acquire serious and fatal primary infection (for example, case 2) as readily as the immunocompromised patient.

Three of the four patients with HHV-6 infection were less than two years old, suggesting primary infections. One case in a three and a half year old child is suggestive of reactivation disease. However, no serologies were available on any of the patients studied, preventing determination of HHV-6 immune status. The three children with primary infections also had high levels of HHV-6 infected cells/ cm^2 . One apparently immunocompetent child (case 2), most likely developed severe HHV-6 pneumonitis and hepatitis. As HHV-6 was identified in the lung, it can be speculated that the liver dysfunction in this patient was also the result of a HHV-6 infection.^{9 10} A severe primary HHV-6 infection was also present in case 4. However, in this case it is hypothesised that congenital HHV-6 infection resulted in immunodeficiency with eventual HHV-6 pneumonitis. This case has been described in detail previously.⁶ Case 1 was also an apparently immunocompetent child with severe primary HHV-6 infection. *Staphylococcus aureus* pneumonia was diagnosed at necropsy. The *S aureus* infection may have been secondary to the HHV-6 infection, as HHV-6 infection can severely compromise the function of phagocytic leucocytes.¹¹

In the three and a half year old child with a low level of HHV-6 infection (29 HHV-6 infected cells per cm^2 of tissue) HHV-6 infection probably reactivated as a result of

Table 1 Characteristics of the study population ($n = 33$)

Age (years)	Sex (M:F)	Immune status	
		Competent	Compromised
≤ 2	7:5	6	6
> 2	11:10	8	13

Table 2 Levels of infection

Case number	HHV-6 infected cells/ cm^2
1	542
2	263
3	29
4	579
All others	0

Table 3 Clinical features

	Case number			
	1	2	3	4
Age	2 years	18 months	3½ years	14½ months
Sex	F	M	M	F
Underlying condition	Congenital anomalies	None	Congenital granulocytopenia	Congenital T cell immunodeficiency
Immune status	Competent	Competent	Suppressed post-BMT	Suppressed
Cause of death	Respiratory failure	Hepatic and respiratory failure	Multiorgan system failure	Respiratory failure
Pathogens identified at necropsy	<i>Staphylococcus aureus</i>	None	Adenovirus	None
Histological diagnosis	Bronchopneumonia; hyaline membranes	Bronchopneumonia; focal haemorrhage	Fibrotic alveolar septa; hyaline membranes; intra-alveolar haemorrhage	Fibrotic alveolar septa; alveolar cells consistent with viral pneumonia

BMT = bone marrow transplantation.

Table 4 Potential pathogens detected

Potential pathogen	Number of patients	Number of patients with HHV-6
No organism	22	2
CMV	4	0
Adenovirus	2	1
Parainfluenza virus	1	0
Aspergillus	1	0
<i>Staphylococcus aureus</i>	1	1
<i>Streptococcus pneumoniae</i>	1	0
<i>Pseudomonas aeruginosa</i>	1	0
Total	33	4

immunosuppression following bone marrow transplantation. The patient was diagnosed at necropsy with systemic adenovirus. Whether a synergism exists between HHV-6 and adenovirus, such as that observed between HHV-6 and HIV,^{12 13} is uncertain. Coinfection with two viruses is common in bone marrow transplant recipients.

The four patients infected with HHV-6 had varying numbers of virus infected cells. HHV-6 infected cells were not found in the remaining patients. These numbers reflect the amount of active HHV-6 infection in the lung tissue at the time of necropsy. Based on the report by Knox,¹⁴ the two values in the 500 range most likely relate to clinically significant levels of infection, and are probably the primary cause of fatal pneumonitis in cases 1 and 4. The presence of only 29 infected cells/cm² in case 3 almost certainly reflects a subclinical level of infection in a patient with a severe adenoviral infection.

The identification of HHV-6 infected cell types as lymphocytes and macrophages suggests that the pathogenic mechanism of HHV-6 pneumonitis is probably not caused by

direct parenchymal cell destruction, but may be more dependent on inflammation and suppression of local immunological responses.

In previous studies, Carrigan *et al*⁴ also demonstrated staining for HHV-6 in macrophages. In contrast, Pitalia *et al*¹⁵ found staining to be predominantly restricted to pneumocytes. However, the former authors used a polyclonal hyperimmune sera, whereas Pitalia *et al* used monoclonal antibodies of uncharacterised epitope reactivity. Perhaps the two antibody preparations have differing specificities.

The spectrum of disease due to HHV-6 has yet to be determined. Asano *et al*⁹ and Tajiri *et al*¹⁰ have reported hepatitis in infants, and Carrigan *et al*⁴ and Knox and Carrigan⁵ have detected HHV-6 infected cells in the lungs of adult bone marrow transplant recipients and patients with AIDS and concomitant interstitial pneumonitis. This study adds more evidence to the role HHV-6 plays, specifically in disease of paediatric patients.

Until easier ways of detecting HHV-6 become available, and testing is not restricted to research laboratories, the prevalence of disease will be underestimated.
