Latest tests for prostatic neoplasia

William J Marshall

Despite being the second most common cancer in males, and one from which mortality is increasing, cancer of the prostate remains in many ways an enigma. For example, little is known of its pathogenesis, although the androgenic hormones are clearly important, the incidence increases with age, and genetic factors also have a role. Furthermore, while its development appears to involve a progression from normal tissue through increasingly severe grades of dysplasia to intraepithelial neoplasia and thence to invasive cancer, there is considerable variation in the rates of progression to invasive disease. Indeed, previously unsuspected prostatic cancer is frequently found at necropsy¹ and in men undergoing surgery for benign disease.

The diagnosis of prostatic cancer is histopathological and generally made from biopsy material. The decision to perform a biopsy may sometimes be based on clinical evidence alone, but for any cancer a diagnostic test to indicate its presence before it is clinically apparent should be of value (depending on the availability of effective treatment and the outcome if treatment is delayed). The screening tests available for prostatic cancer are digital rectal examination, transrectal ultrasound, and serum prostate specific antigen (PSA). Neither of the first two is sufficiently reliable on its own. In practice, measurements of PSA are used to decide whether to perform ultrasound examination as a preliminary to possible biopsy. However, PSA measurements can be used in several ways.

Unusually for a common tumour, there has long been a blood borne marker for prostatic cancer, namely prostatic acid phosphatase (PAP), first described in 1938.² However, PAP was not sufficiently sensitive or specific to be useful in screening, although it was of value in monitoring the response to treatment of patients with invasive disease. Prostate specific antigen (PSA) was identified in semen some 30 years later, and first isolated from prostatic tissue in 1979.³ The first report of its potential as a tumour marker for prostatic cancer appeared shortly after⁴ and within a short time PSA had become the preferred marker and PAP became regarded as obsolete. Indeed, PAP has by now been deleted from most laboratories' repertoires.

But how reliable is PSA as a test for prostatic cancer? Are multiple measurements more reli-

able than single measurements? Does the measurement of free PSA offer any advantage over that of bound PSA? And will PSA eventually go the way of PAP—are there any other tests for prostatic cancer in the offing? There are thousands of research papers on this topic and any review must necessarily be highly selective. Several more comprehensive reviews on screening for and managing prostatic cancer have been published recently.⁵⁻⁸

Origin of PSA

PSA is a serine protease secreted by cells lining the acini and ducts of the prostate. Its function is to hydrolyse the seminal fluid coagulum and assist in the liberation of spermatozoa. The small concentrations normally detectable in the blood are thought to reach it primarily by diffusion, passing from the ductal system across the prostatic stroma into capillaries and lymphatics. In prostatic disease, the anatomical disruption facilitates this process. The name PSA is actually misleading since the protein has been detected in various exocrine secretions; this is not of significance in men, but the measurement of PSA in breast secretions is being investigated as a possible screening test for carcinoma of the breast in women.

Nature and isoforms

PSA is a glycoprotein of molecular mass approximately 33 kDa. The native form is designated PSA-B; PSA-A is an active form with reduced carbohydrate content and PSA-C, PSA-D, and PSA-E have modified (internally cleaved) peptide chains and little enzymatic activity. Most PSA in seminal fluid is free, but in the blood, it binds extensively to the protease inhibitors α_2 macroglobulin and α_1 antichymotrypsin (ACT).⁹ This protein binding in plasma is a phenomenon common to all proteases and presumably is a protective mechanism. For PSA, it has considerable implications for the assay of the protein. When PSA is bound by α_2 macroglobulin, it becomes encapsulated by the protein and its epitopes are hidden, with the result that it is not detected in immunoassays for PSA. Binding to ACT leaves most of the PSA epitopes exposed. Assays may therefore measure total (ACT bound + free) PSA, or either ACT bound or free PSA alone. The performance of the commercially available assays has recently been comprehensively reviewed.⁵ Early assays purported to measure total PSA

but assays for free PSA are now widely available and assays which will measure free and total simultaneously are being developed.

Reference intervals

Although initially thought to be absent from the plasma when there is no prostatic disease, it is now clear that PSA is present in the plasma of healthy men, with a concentration range that is skewed to the right. PSA concentrations tend to increase with age, largely as a result of the increase in the size of the gland with age.¹⁰ Unfortunately, as with all other tumour markers, the concentrations of PSA found in healthy men and those found in the presence of cancer overlap: the concept of a "normal range" (strictly, "reference interval") in relation to PSA is thus inappropriate. Indeed, men may be healthy in that they do not have symptoms of prostatic disease and have a clinically or ultrasonographically normal prostate and yet still be harbouring cancer: the diagnosis can only be excluded on the basis of detailed necropsy examination. It is thus impossible to be certain that some members of a group used to define a reference interval may not have cancer. Furthermore, benign prostatic hypertrophy is a common condition so prostatic cancer may be present in a patient with benign disease and be contributing to the PSA present in the plasma.

PSA concentrations may also be increased in prostatitis and acute retention of urine. Digital rectal examination causes a small, transient increase (approximately 5%, for up to 48 hours).¹¹ The reported effects of recent ejaculation are inconsistent. There is no significant diurnal variation, but intraindividual variation can be more than 20%.¹²

When PSA measurement is used for screening or diagnosis (but not for monitoring known cancer), what is required is a measure of the probability that any given concentration can be associated with cancer. These can be used to define "action levels" to direct management. Ideally, the utility of these action levels should be audited with regard to their effect on outcome. The existence of different assays based on different antibodies and using different calibrators means that the results obtained using any one assay may not be strictly comparable with those obtained with another. In practice, with measurements of total PSA these differences probably matter little, and a plasma PSA concentration of up to 4 µg/litre has usually taken as implying a very low risk of cancer (though not excluding it), while concentrations over 10 µg/litre the probability of cancer becomes higher than that of benign disease. Men with concentrations at screening > 10 µg/litre will usually be further investigated; those with concentrations below a lower cut off—usually taken as 4 µg/litre, although values as low as 2.5 µg/litre have been suggested—will not. It is in the concentration range of 4 to 10 µg/litre that uncertainty is greatest.

Improving the performance of PSA measurements in screening and diagnosis

The ideal screening or diagnostic test would be positive in all individuals harbouring the

disease in question (high sensitivity—that is, no false negatives) and negative in all unaffected individuals (high specificity—that is, no false positives). Given the overlap in the ranges of concentration of PSA that are seen in apparently healthy men and those with (histologically) proven cancer, PSA—in common with all other tumour markers—cannot be both 100% sensitive and 100% specific. Moving the cut off point or action limit to higher concentrations would increase specificity at the expense of sensitivity, while moving the cut off point lower has the opposite effect.¹³ Various strategies have been examined in attempt to improve the sensitivity of PSA measurements without compromising specificity.

Age related cut off points

Since plasma PSA concentration increases with age, the application of the same cut off in older men as in younger would have the effect of improving sensitivity but at the expense of specificity. Applying a higher cut off in older men would have the opposite effects. Age related cut off points have been proposed¹⁰ but are little used. Although a relatively lower cut off in younger men would detect more cancer and possibly be of greater long term benefit, more men would require further testing to establish the diagnosis. On the other hand, a relatively higher cut off in older men would result in decreased diagnosis of potentially curable (but not necessarily life threatening) tumours but less further testing—important not only for the individual but in economic terms, given the larger number of older men with raised PSA concentrations because of benign disease. These predictions were confirmed by the results of a study of over 4700 men.¹⁴ However, the prevalence of benign disease and cancer both increase with age, and the conclusions of a study of over 6600 men were that using a cut off for further investigation of 4 µg/litre at all ages gives a similar biopsy rate and frequency of detection of cancer.¹⁵ The arguments are the typical ones of screening—that is, the balancing of economic factors against possible clinical benefit, with the latter being uncertain on an individual basis.

PSA "density"

This concept relates serum PSA concentration to the size of the prostate as estimated using transrectal ultrasonography. There is some evidence that this technique increases sensitivity, particularly in the "grey" zone of total PSA 4–10 µg/litre.^{16, 17} However, the choice of cut off is critical. Also, measurements of prostatic size by ultrasound have poor accuracy (magnetic resonance imaging is more accurate but not practical) and in practice the use of PSA density has not been shown to have a consistent advantage over the use of a simple cut off based on concentration alone.¹⁸

PSA velocity

In using cut off points to determine further management, a decision is being made about an individual based on observations on others. Repeating measurements of PSA in an

individual allows comparison with his own previously determined values. PSA concentration increases linearly with time (at about 0.12 µg/litre/year) as a result of benign hypertrophy; the rate is higher and the increase exponential in cancer and relatively higher with more aggressive tumours.¹⁹ Either an increase in velocity or a high velocity (> 20% annual increase)²⁰ is thus suggestive of cancer. Problems with this technique include the difficulty of ensuring comparability of measurements made over a period of years (requiring a very stable assay system) and the innate intraindividual variation of PSA measurements.¹² This latter means that an apparent increase in PSA from 4.0 to 5.2 µg/litre has a probability of less than 0.95 of being a true increase. Ideally, PSA velocities should be based on sets of several measurements in order to reduce the effect of this variation. PSA velocity has no better sensitivity than simple cut offs but has better specificity. Used alone, however, it might delay diagnosis, since a rise can only be discerned in retrospect. On the other hand, its use should allow earlier detection of cancers since an increase in PSA might be significant even if the absolute value remains below 4 µg/litre. Whether this would have any effect on outcome is another matter.

Free PSA and free/bound PSA ratio

Total, bound, and free PSA concentrations increase in parallel with age, so that the ratio of free to bound remains constant.²¹ The most promising advances in the use of PSA in the diagnosis of prostatic cancer stem from the discovery that the proportion of protein bound PSA in the plasma is higher in cancer than in benign disease²² (there is evidence that ACT synthesis often occurs in neoplastic prostatic tissue but only rarely in benign tissue).²³ Although there have been methodological problems with the free PSA assays, the use of ratios does promise enhanced sensitivity and specificity, albeit at the cost of doing two measurements and the increased imprecision that the use of a ratio of two concentrations implies.

Ratios would not help in individuals found to have high total PSA (> 10 µg/litre) since they would always require further investigation, and—except possibly in young men—would be of little value with low total concentrations. The greatest benefit would be in the intermediate group, for example men with a total PSA of between 4 and 10 µg/litre, where the finding of a high free/total ratio might spare men a biopsy and allow a more conservative approach (for example, annual repeat PSA measurements and digital rectal examination), while a low ratio would be an indication for transrectal ultrasound examination and biopsy. The results of several studies have confirmed this prediction.^{24 25}

This topic is presently the subject of intensive research.²⁶ It appears that measurement of the free/bound PSA ratio is a significant improvement over the measurement total PSA alone for the diagnosis of early prostatic cancer.

Relating the free/bound PSA ratio to prostate volume may help further.²⁷ While it must follow that if fewer biopsies are performed some cancers will be missed, however many might have proven negative, it is also important to avoid unnecessary biopsies and operations.

Are there alternatives to PSA?

Several substances other than PSA have been detected at increased concentration in the plasma of patients with prostatic cancer (for example, creatine kinase BB, α -fetoprotein, and carcinoembryonic antigen). None seems likely to supplant PSA. What can be predicted is that assays for PSA will continue to be improved as manufacturers compete in an increasingly informed market place; that research into the best way to apply PSA measurements will continue; and that as data from individual groups continue to be published, systematic reviews will be performed which may further help to define the role of PSA.

Conclusion

At present, there is no convincing evidence of consistent clinical benefit from the early detection of prostatic cancer²⁸ although this is not equivalent to there being evidence of no benefit.²⁹ Trials are currently under way but will not be completed until the early years of the next century.^{30 31} The advent of PSA has raised the question of whether, since prostatic cancer is so common, asymptomatic men should be routinely screened by PSA measurement. In the USA, doing this has led to a considerable increase in the number of men having biopsies and prostatectomies. Advice in the United Kingdom is that routine screening is not appropriate⁶ but this may not stop patients requesting it.³² Laboratories can anticipate increasing numbers of requests for PSA and should modify their practice with regard to the precise choice of technique according to the evidence.
