The borderline cervical smear: colposcopic and biopsy outcome

Awatif Al-Nafussi, Gemma Rebello, Raja Al-Yusif, Euphemia McGoogan

Abstract

Aims—To review the outcome of women referred with smears showing borderline nuclear change (BNC), and to determine any differences in outcome if BNC was persistent, preceded by dyskaryosis, or followed treatment for cervical intraepithelial neoplasia (CIN). In addition, to determine criteria that might permit delineation of a BNC subtype, predictive of CIN.

Methods—The records of 178 women referred for colposcopy in 1993, with last smear showing BNC, were obtained from our laboratory database. The cytology, colposcopy, and biopsy follow up for a five year period were also obtained. The patients were divided into three categories according to their smear status before the last referral borderline smear: category 1, persistent BNC (n = 39); category 2, BNC preceded by dyskaryotic smears (n = 100); and category 3, BNC after treatment for CIN (n = 39). The referral borderline smears were reviewed on cases with negative outcome and those with a biopsy diagnosis of CIN2 and CIN3.

Results—In 50 women (28%) no biopsy was deemed necessary after colposcopic assessment. The biopsy results in the remaining 128 (72%) women were as follows: normal in 18 (10%), koilocytosis in 12 (7%), CIN1 in 45 (25%), CIN2 in 32 (18%), and CIN3 in 21 (12%) women. High grade lesions (CIN2, CIN3) were seen on biopsy in 14 of 39, 33 of 100, and six of 39 cases in category 1, category 2, and category 3, respectively. Blind review of the referral borderline smears from 53 women with a biopsy diagnosis of high grade lesions (32 CIN2, 21 CIN3) confirmed they were borderline in 23, upgraded them to mild dyskaryosis in 15, and found that 14 cases of isolated moderate or severe dyskaryotic cells had been missed originally. The borderline change was in mature squamous cells in five of 23 and in immature metaplastic epithelium in 18 of 23 cases. After smear review in 68 women with negative outcome, 36 smears were reclassified as negative in keeping with inflammation and atrophy, three were considered unsatisfactory, one was

upgraded to CIN1, and 28 were confirmed as BNC. Of the latter, 25 of 28 were in mature squamous cells. The five year follow up on women with negative colposcopy (n = 50), negative loop excision of transformation zone (LETZ) (n = 18), and LETZ with koilocytosis (n = 12) showed subsequent high grade CIN on LETZ in 16, 0, and two patients, respectively.

Conclusions—On referral of women for colposcopy with last smear showing BNC, the outcome was high grade CIN in over 30% of cases, irrespective of whether the borderline smear was preceded by another borderline smear or by a dyskaryotic smear. In contrast, in those referred because of BNC after treatment of CIN, high grade CIN was seen less frequently (15% of cases). Furthermore, in cases that necessitated loop excisions, high grade CIN was seen in 41%. This study also showed that BNC associated with inflammation or atrophy, or BNC in mature squamous cells, appears to have lower predictive value for CIN than those cases where BNC is associated with immature metaplastic epithelium. The use of terms such as “BNC favour reactive” for the former and “BNC favour dyskaryosis” for the latter is recommended, together with follow up by cytology and colposcopy, respectively.

(J Clin Pathol 2000;53:439–444)

Keywords: borderline nuclear abnormality; cervical cytology

The effectiveness of cervical screening programmes is measured by the reduction in the incidence of, and deaths from, cervical cancer. In an effort to categorise equivocal cases and minimise false negative results, laboratories utilise a term such as borderline nuclear changes (BNC).^{1–3} This is used for smears with nuclear abnormalities that cannot be ascribed with certainty to a benign process but are not sufficient for an unequivocal diagnosis of squamous dyskaryosis. In the Bethesda classification, the term “atypical squamous cells of uncertain significance (ASCUS)” is used for this purpose.⁴ However, the ASCUS classification excludes cases of human papillomavirus (HPV) infection, which form a large proportion of the cases classified as BNC.³

Table 1 Categories according to smear status before the last referral borderline smear

Category	Description	n = 178
1	Those with at least 1 other borderline smear	39 (22.5%)
2	Those with 1–2 mild or moderate dyskaryosis	100 (55%)
3	Those who had treatment for CIN	39 (22.5%)

CIN, cervical intraepithelial neoplasia.

Table 2 The outcome of women referred for colposcopy with BNC

Total No.	178 women
No biopsy taken	50 (28%)
Biopsy taken	128 (72%)
Biopsy negative	18 (10%)
Biopsy koilocytosis	12 (7%)
Biopsy CIN1	45 (25%)
Biopsy CIN2	32 (18%)
Biopsy CIN3	21 (12%)
Biopsy CIN2,3	53 (30%)

BNC, borderline nuclear change; CIN, cervical intraepithelial neoplasia.

Nonetheless, the diagnosis of BNC/ASCUS has no clear cut morphological criteria.³ Inevitably, this category includes cases that ultimately prove to be inflammatory, reparative, or atrophic changes, as well as cases of cervical intraepithelial neoplasia (CIN) or the Bethesda equivalent SIL (squamous intraepithelial lesion). Borderline smear reports can form 5–20% of the workload of cervical cytology laboratories world wide, but the accepted standard in the UK is for BNC and mild dyskaryosis combined to be in the region of 5.5%.⁵ The optimal management of women with low grade abnormalities detected on smears remains controversial. The current practice in the UK is to request a repeat smear in 6–12 months for first and second BNC and a referral for colposcopy for the third one. For a first mild dyskaryosis, the recommendation is to repeat in three to six months and for a second to refer for colposcopy.² Referral of women for colposcopy can cause high anxiety and unnecessary treatment with possible complications.⁶

There have been recent reports on the risk of CIN in women with smears showing BNC. Most of these reports suggest that CIN is found in a large proportion of subsequent smears or biopsies.^{7–15} Soofer and Sidawy found SIL on follow up smears in 24% of women with ASCUS compared with 3.9% in those with smears showing reactive changes and 1.6% of those with negative smears.¹⁴ Similarly, Stastny *et al* found a significant difference in the risk of developing SIL between women with a negative smear and those with an ASCUS smear (6% *v* 24.3%).¹⁵

The Edinburgh University department of pathology serves a population of approximately 250 000 women in the cervical screening age

group (20–60 years) and receives over 85 000 cervical smears and 2500–3000 cervical biopsies annually. The borderline smear category constitutes 5–7% of our workload, and nearly 200 to 300 women are referred annually for colposcopy after a BNC.

The aims of our study were: (1) to determine the outcome of women referred for colposcopy with smears showing BNC; (2) to find out whether the outcome is different depending on whether BNC was persistent, preceded by dyskaryosis, or followed treatment for CIN; and (3) to see whether a subtype of BNC can be identified that carries a higher predictive value for CIN.

Materials and methods

DATA COLLECTION

The records of 178 consecutive women referred for colposcopy at the Edinburgh Royal Infirmary in the year 1993, with a referral cervical smear showing BNC, were obtained from the laboratory database. Subsequent and prior biopsy and/or smear records with five year follow up were also obtained.

The patients were divided into three categories according to the smear history before the referral BNC (table 1): category 1, BNC preceded by at least one other borderline smear; category 2, BNC preceded by one or two dyskaryotic smears; and category 3, BNC discovered at follow up after treatment for CIN.

SMEAR REVIEW

The referral borderline smears from 68 women who had negative outcome (either on colposcopy or biopsy) and from 53 women with a biopsy diagnosis of high grade CIN were selected for critical review independently (and blind to the colposcopic outcome) by two of the authors (GR and RAL). When the cellular changes were inconsistent with BNC, the smears were reclassified into negative with inflammatory or atrophic changes, or dyskaryotic. When BNC was confirmed, an attempt was made to classify it into either BNC in mature squamous cells or BNC in immature metaplastic cells.

Results

Table 2 shows the outcome of 178 women after referral for colposcopy. No colposcopic abnormality was found and biopsy was deemed unnecessary in 50 women (28%). In the remaining 128 women, loop excision of transformation zone (LETZ) was performed. The biopsy diagnoses in this group of women were as follows: normal in 18 (10%), koilocytosis in 12 (7%), CIN1 in 45 (25%), CIN2 in 32 (18%), and CIN3 in 21 (12%) women. CIN2 and CIN3 together constituted 30% of the total number of women (53 of 178) referred for colposcopy and 41% of those who had LETZ.

According to the smear history before the referral borderline smears, there were 39 women (22.5%) in category 1 (those with at least one other borderline smear), 100 (55%) in category 2 (those preceded by one or two

Table 3 Outcome of the three categories

Category	n	Negative	Koilocytosis	CIN1,2,3	CIN2,3
1 Persistent BNC	178	68 (44%)	12	98 (56%)	53 (28%)
2 BNC preceded by dyskaryosis	39	13 (33%)	5 (13%)	21 (54%)	14 (36%)
3 BNC after treatment for CIN	100	32 (32%)	5 (5%)	63 (63%)	33 (33%)
	39	23 (59%)	2 (5%)	14 (44%)	06 (15%)

dyskaryotic smears), and 39 (22.5%) in category 3 (those in whom BNC followed treatment for CIN) (table 1). Table 3 shows the colposcopic and biopsy outcome of these three groups. A negative outcome was found in 13 of 39 (33%) of those in category 1, 32 of 100 (32%) of those in category 2, and in 23 of 39 (59%) of those in category 3. High grade CIN was found in 14 of 39 (36%), 33 of 100 (33%), and six of 39 (15%) of those in categories 1, 2, and 3, respectively.

SMEAR REVIEW

Table 4 shows the results of reviewing 121 borderline smears from 68 women with negative colposcopic outcome and 53 women with biopsy diagnosis of high grade CIN. The left hand column shows the review results of these

Figure 1 Isolated collection of moderately and severely dyskaryotic cells were misinterpreted as immature metaplastic cells with borderline nuclear change. Biopsy diagnosis cervical intraepithelial neoplasia 3.

Figure 2 Isolated metaplastic cells showing enlarged nuclei with irregular borders, and coarse chromatin but no hyperchromasia (compared with adjacent polymorphs). These were reported as borderline nuclear change. Biopsy diagnosis cervical intraepithelial neoplasia 3.

Figure 3 Nuclear enlargement, variation, and hyperchromasia in mature squamous cells, diagnosed as borderline nuclear change. Biopsy outcome with five years follow up is negative.

borderline smears. BNC was confirmed in 51 women (42%), reclassified as negative in 36 (30%), upgraded to mild dyskaryosis in 16 (13%), and upgraded to moderate and severe dyskaryosis in 14 (12%). Four smears (2%) were reclassified as unsatisfactory. The middle column shows the smear review results of 68 women with negative colposcopic outcome or in whom biopsies were negative. In 28 women (41%) BNC was confirmed, in 36 (53%) the smears were reclassified as negative, in one (2%) the smear was upgraded to mild dyskaryosis, and in three (4%) smears were considered to be unsatisfactory. The right hand column shows the review results of 53 smears from women who had subsequent biopsy diagnosis of CIN2 and CIN3. The diagnosis of BNC was confirmed in 23 (43%) smears, upgraded to mild dyskaryosis in 15 (28%), considered unsatisfactory in one (2%), and isolated moderately or severely dyskaryosis cells had been missed in 14 (27%).

Table 5 shows the reasons for reclassifying 36 of 68 borderline smears as negative. In 16 of cases (44%), the changes were considered to be inflammatory in nature, and in another 16 cases (44%) they were thought to result from the presence of a few cells with enlarged nuclei or showing enlarged nuclei that lacked any chromatin abnormality. In the remaining four (11%) the changes were the result of post-menopausal atrophy.

The smears that were upgraded to moderate or severe dyskaryosis were generally of poor quality and showed either a few dyskaryotic cells (fig 1), pale dyskaryosis (fig 2), or micro-biopsy.

Figure 4 Nuclear enlargement and hyperchromasia in immature squamous cells diagnosed as borderline nuclear change. Biopsy outcome cervical intraepithelial neoplasia 3.

Table 6 Five years follow up of 80 women with no biopsy, or a biopsy diagnosis of negative or koilocytosis

	n	Persistent BNC	Persistent dyskaryosis	CIN2/3 on biopsy
No biopsy	50 (28%)	3 (6%)	5 (10%)	4 (8%)
Negative	18 (10%)	0	1 (6%)	0
Koilocytosis	12 (7%)	1	0	2 (17%)

BNC, borderline nuclear change.

BNC was confirmed in 51 smears, of which 30 (59%) were in mature squamous cells (fig 3) and 21 (41%) were in immature metaplastic cells (fig 4). When these subtypes were matched with the outcome, the following figures emerged: BNC in mature squamous cells was found in 25 of 28 (89%) of those with negative outcome and in five of 23 (22%) of those with high grade outcome. On the other hand, BNC in immature metaplastic cells was seen in three of 28 (11%) and 18 of 21 (78%) cases with negative and high grade CIN outcome, respectively.

SMEAR FOLLOW UPS

Table 6 illustrates the results of the five year cytology/biopsy follow up of 80 women who had negative outcome (no biopsy, 50; negative biopsy, 18; koilocytosis, 12). Persistent BNC was seen in three of 50 (6%), dyskaryosis in five of 50 (10%), and high grade CIN on further biopsy in four of 50 (8%) cases with no biopsy on initial colposcopic assessment. Persistent dyskaryosis on smears was seen in only one of 18 (6%) women who had negative biopsy results. Cervical intraepithelial neoplasia grade 2 was found on further biopsy in two of those (17%) with an original biopsy diagnosis of koilocytosis.

Discussion

One of the greatest clinical dilemmas associated with cervical screening is the management of low grade cytological abnormalities, namely BNC and mild dyskaryosis. These abnormalities are of concern because in a small but important number, they reflect the presence of high grade CIN.⁷⁻¹⁵ However, in contrast, many women are being treated unnecessarily, resulting in emotional stress and unjustifiably high costs to the National Health Service that could be used for other more pressing medical problems.

Our study has shown that none of our patients who had been referred because of repeated BNC had invasive disease, and nearly half had negative outcome. It also showed that irrespective of whether a borderline smear is preceded by another borderline smear, or by mildly or even moderately dyskaryotic cells, the outcome was high grade CIN in nearly one third of the cases. However, when borderline smears followed LETZ, high grade CIN was less common (15% of cases). This study has also shown that not all women who were referred for colposcopy because of persistent BNC underwent loop excision. In 50 (28%) of our patients no biopsy was taken because the cervix appeared normal at the time of initial referral for colposcopy. None of these women had invasive disease after five years of follow

up, but 10% had subsequent dyskaryosis on further smears and 8% had biopsy diagnosis of high grade CIN (table 6). This might reflect the limitations of colposcopy in detecting CIN. Of the remaining 128 women who had a colposcopic abnormality that necessitated LETZ, 53 of 128 (41%) did have high grade CIN on biopsy. This is almost identical to a recent study of 172 women who were referred for colposcopy because of persistent mild dyskaryosis or persistent borderline changes, 44% and 41% of whom were found to have high grade CIN, respectively (G Rebello, *et al*, 1999, personal communication). Other reports on the follow up of patients with ASCUS have yielded SIL rates ranging from 31% to 61%.⁷⁻¹⁶ The high CIN rate after persistent BNC might reflect the fact the BNC is an extremely difficult diagnostic area and shows poor interobserver and intra-observer consistency.^{3 17} In one report,¹⁸ five expert pathologists independently reviewed 200 smears previously classified as ASCUS. The use of Bethesda criteria resulted in reclassification of most cases as negative or SIL. However, not one smear was diagnosed as ASCUS by all five members, highlighting the difficulty in diagnostic reproducibility. However, despite the problems in consistency of diagnosis, we can conclude that persistent BNC is a predictor of high grade CIN in a considerable number of women. Nonetheless, whether we are underestimating some of the nuclear or cytological features of high grade dyskaryosis in favour of BNC remains to be seen. In our study, we upgraded borderline smears to CIN1 in 13% of cases, and moderate and severe dyskaryosis were missed in 10%. It appears, therefore, that false negative smears are still a problem. Some of the reasons for missing high grade dyskaryosis in our study were: the presence of only a few abnormal cells, pale dyskaryosis, and small microbiopsy like aggregates. These were often found in suboptimal smears. This problem has been highlighted recently by Mitchell and Medley¹⁹ and O'Sullivan *et al*,²⁰ who have emphasised the type of high grade smear that is likely to be reported incorrectly as negative under normal screening conditions. In a recent study, Bergeron and colleagues²¹ reviewed smear histories of 585 women with biopsy confirmed CIN3 and found 14.8% false negative smear diagnoses; on reviewing these smears, they found 41% to be abnormal, half of which were of high grade abnormality.

Does a subtype of BNC with more predictive value for high grade CIN exist? It has been shown that metaplastic squamous cells with BNC/ASCUS carry a higher risk of CIN being detected on colposcopy and biopsy.^{22 23} In our study, 18 of 23 (77%) of our borderline smears with a biopsy outcome of high grade CIN showed atypical nuclei in immature squamous cells compared with three of 28 (11%) of those with negative outcome. Bethesda workshop participants suggested initially that the diagnosis of ASCUS should be qualified as "favour reactive" or "favour squamous intraepithelial lesion (SIL)". The literature on this subject is

varied but generally concludes that patients with ASCUS in whom a dysplastic process is favoured have a higher rate of SIL/cancer on follow up than do patients in whom a reactive process is favoured.²³ A subcategorisation of ASCUS has been advocated with terms such as: "equivocal low grade SIL (LSIL)", "cannot rule out LSIL", "low grade potential", or "minimal changes" for cases where the most important abnormality is LSIL, and that might represent a reactive process or an early cytological manifestation of HPV infection. The terms "equivocal high grade SIL (HSIL)", "cannot rule out HSIL", "high grade potential", or "inconclusive" have been advocated for those cases that might be a high grade lesion or carcinoma, to distinguish them from the (more benign) equivocal LSIL category.²⁴

In our study, we reclassified 36 of 68 (53%) samples originally classified as BNC to negative (table 5). Of these, 16 (44%) were associated with inflammation and four (11%) with postmenopausal atrophy. In the remaining 16 (44%), the nuclear abnormalities were seen in only a few cells and were in the form of enlarged nuclei lacking any chromatin abnormality. In the past, there was a category of smear report called "inflammatory changes" and the recommendation was early repeat smear. In their update, the British Society for Clinical Cytology and Royal College of Pathology representatives agreed to abolish this category in favour of either negative or borderline nuclear changes.³ We feel that many people are cautious and call what would previously have been called inflammatory change, BNC. This has resulted in a major increase in the size of the borderline category and a huge increase in referrals for colposcopy. The other problem is the atypical cells associated with postmenopausal atrophy (C Crum C, ES Cibas. 13th world congress of academic and environmental pathology, Nice, 1998).²⁵⁻²⁷ Smears from these women are usually air dried and show apparent nuclear enlargement, a pronounced inflammatory component, and clusters of small dark bare nuclei that are difficult to interpret. A helpful means of assessing atrophy related atypia is the "oestrogen test", whereby application of local oestrogen cream results in maturation of the squamous cells and easier interpretation of the cell morphology. However, the atypia may persist in spite of subsequent negative biopsy findings.²⁸⁻²⁹ Abati and colleagues²⁵ have found that nuclear hyperchromasia and irregularity in contours rather than nuclear enlargement alone seem to be the most reliable cytological criteria for the diagnosis of genuine dyskaryosis in atrophic smears. In countries where there are organised cervical screening programmes it is considered unethical to have a high proportion of false positive smears, which result in over-treatment and an unnecessary burden for women participating in cervical screening.

It is clear from these observations that some subtypes of borderline smears might have less predictive value for CIN than others. In view of this, we support the proposal of using phrases

such as "BNC favour reactive", or "BNC favour low or high grade CIN". In this way, we could cut down considerably on the number of women referred unnecessarily for colposcopy by advising follow up by cytology only in the former category, and referral for colposcopy in the latter group. On applying these recommendations one would be in a position to assess prospectively the outcome of the various subtypes.

Further studies might be needed to provide more information to distinguish true precursor lesions from those that have no clinical relevance.

In summary, of all patients who were referred for colposcopy because of borderline smears, 38% (50 + 18 = 68) were referred unnecessarily, 7% (12 of 178) had koilocytosis, and the remaining 55% (98 of 178) had CIN, with 30% showing high grade lesions (CIN2 and CIN3). No women had invasive disease. Our study also emphasises the problem of false negative smears and identifies a group of apparent borderline changes that are truly dyskaryotic, and furthermore identifies a subgroup of BNC that is more predictive of high grade dyskaryosis.
