J Clin Pathol 2004;57:728–734. doi: 10.1136/jcp.2003.012989

Background: Little is known about statins in the prevention of dyslipidaemia induced renal function decline. The secondary coronary heart disease (CHD) prevention GREACE study suggested that dose titration with atorvastatin (10–80 mg/day, mean dose 24 mg/day) achieves the national cholesterol educational programme treatment goals and significantly reduces morbidity and mortality, compared with usual care.

Aims: To report the effect of statin on renal function compared with untreated dyslipidaemia in both treatment groups.

Methods/Results: All patients had plasma creatinine values within the reference range $< 115 \mu\text{mol/litre}$ (13 mg/litre). The on study creatinine clearance (CrCl), as estimated (for up to 48 months) by the Cockcroft-Gault formula, was compared within and between treatment groups using analysis of variance to assess differences over time. Patients from both groups not treated with statins (704) showed a 5.2% decrease in CrCl ($p < 0.0001$). Usual care patients on various statins (97) had a 4.9% increase in CrCl ($p = 0.003$). Structured care patients on atorvastatin (783) had a 12% increase in CrCl ($p < 0.0001$). This effect was more prominent in the lower two quartiles of baseline CrCl and with higher atorvastatin doses. After adjustment for 25 predictors of all CHD related events, multivariate analysis revealed a hazards ratio of 0.84 (confidence interval 0.73 to 0.95; $p = 0.003$) with every 5% increase in CrCl.

Conclusions: In untreated dyslipidaemic patients with CHD and normal renal function at baseline, CrCl declines over a period of three years. Statin treatment prevents this decline and significantly improves renal function, potentially offsetting an additional factor associated with CHD risk.

Accepted for publication 21 October 2003

It has been reported recently that of 4483 apparently healthy men participating in the physicians' health study with an initial serum creatinine (SCr) $< 115 \mu\text{mol/litre}$ (13 mg/litre), those with low high density lipoprotein (HDL) cholesterol and high non-HDL cholesterol had double the risk of renal insufficiency, during longterm follow up, after adjusting for other risk factors.¹ Although studies in animal models have found a favourable effect of lipid reduction on the progression of renal disease,^{2–4} the results of trials in humans are less clear, because most controlled trials have been too small to make a definitive conclusion.⁵ The Helsinki heart study,⁶ a primary prevention trial, was the first survival study with hypolipidaemic drug treatment to address the issue. Authors reported that dyslipidaemia increased SCr values in patients with normal baseline renal function, both in the placebo and gemfibrozil subgroups, suggesting that treatment with a fibrate could not prevent the deterioration of renal function. Fibrates may increase SCr concentrations, although gemfibrozil, which was used in the Helsinki heart study, usually does not exert this adverse effect.⁷

"Although studies in animal models have found a favourable effect of lipid reduction on the progression of renal disease, the results of trials in humans are less clear, because most controlled trials have been too small to make a definitive conclusion"

The recently published MRC/BHF heart protection study (HPS) subgroup analysis for participants with diabetes

mellitus⁸ showed that unadjusted SCr concentrations increased in all patients, with or without diabetes mellitus, over a period of 4.6 years. However, allocation to simvastatin (40 mg/day) significantly decreased the rise in SCr values in patients with and without diabetes mellitus.⁸

The Greek atorvastatin and coronary heart disease evaluation (GREACE) study,^{9–10} a prospective, randomised, target based, open label secondary coronary heart disease (CHD) prevention trial, suggested that structured management of dyslipidaemia with dose titration of atorvastatin can achieve the national cholesterol educational programme (NCEP) treatment goals^{11–12} and provide significant reductions in morbidity and mortality, in comparison with usual care. In the present subgroup analysis of the GREACE results, we report the longterm effect of structured versus usual care (intention to treat analysis), and the effect of statin versus no hypolipidaemic drug treatment (treatment based analysis) on estimated creatinine clearance (CrCl).

Abbreviations: ACE, angiotensin converting enzyme; C, cholesterol; CHD, coronary heart disease; CI, confidence interval; CrCl, creatinine clearance; GFR, glomerular filtration rate; GREACE, Greek atorvastatin and coronary heart disease evaluation; HDL, high density lipoprotein; HPS, heart protection study; HR, hazard ratio; K/DOQI, kidney disease outcomes and quality initiative; LDL, low density lipoprotein; NCEP, national cholesterol educational programme; SCr, serum creatinine; TG, triglyceride

METHODS

Study design, patients, and methods

The design of the GREACE study and the findings on mortality, morbidity, cost effectiveness, and longterm safety have been described previously.^{9–13} In brief, the patients were men (78%) and women (22%) with established CHD, aged < 75 years old (mean, 58.3). Their serum low density lipoprotein cholesterol (LDL-C) and serum triglyceride (TG) concentrations had to be > 2.6 mmol/litre (1000 mg/litre) and < 4.5 mmol/litre (4000 mg/litre), respectively. Patients with recent acute coronary syndromes were not excluded. The study received local ethical approval and informed consent was obtained from all patients before enrolment. All patients attended the atherosclerosis unit of the University Hospital, Thessaloniki, Greece, and if eligible were randomised either into the structured care group, followed up by the university clinic, or into the usual care group, followed up by heart specialists or general practitioners of the patient's choice outside the hospital. In the structured care group, the starting dose of atorvastatin was 10 mg/day. With evaluations every six weeks, the dose of atorvastatin was titrated up to 80 mg/day for patients not reaching the NCEP LDL-C goal (< 2.6 mmol/litre; 1000 mg/litre) with lower dosages. Patients in the usual care group were treated according to their physician's standard of care. Usual care included life style changes, such as low fat diet, weight loss, and exercise, in addition to all necessary drug treatment and lipid lowering agents. Atorvastatin was not excluded from the usual care group. After dose titration, patients were followed for a mean three year period, with visits every six months. SCr was measured using the Jaffé method (Olympus Diagnostica GmbH; Clare, Ireland) and the normal range was 55–115 µmol/litre (6–13 mg/litre). CrCl was estimated from the SCr values by the Cockcroft-Gault formula. This formula includes factors that correct for age, weight, and sex.¹⁴

Endpoints

Primary endpoints were all cause and coronary mortality, coronary morbidity (non-fatal myocardial infarction, revascularisation, unstable angina, and congestive heart failure), and stroke. Moreover, the composite endpoint "all vascular events" comprising all primary endpoints (all coronary events plus stroke) was used. Secondary endpoints were safety and efficacy of longterm atorvastatin treatment, cost effectiveness of structured care, and the assessment of the relation between CHD risk factors and clinical outcomes. The present analysis based on SCr is post hoc.

Statistical analyses

Both intention to treat and treatment based analyses of all patients randomised to the structured or usual care groups were performed. CrCl was assessed at baseline, at the sixth treatment week, and every six months thereafter. On study CrCl values were compared with those at baseline, using analysis of variance (ANOVA) to assess differences over time within and between treatment groups. A univariate analysis was performed initially, including 25 predictors of CHD related events. Then, after removal of six predictors with a $p > 0.10$, 19 predictors were included in a multivariate Cox predictive model, involving backward stepwise logistic regression, for all CHD related events. All predictors were recorded as categorical factors (0–1), except for CrCl, which was analysed as a continuous parameter. All univariate or multivariate analyses were performed with a 5% stepwise increase or reduction of CrCl from baseline. A two tailed value of $p < 0.05$ was considered significant. The Statgraphics Plus (Statgraphics, Rockville, Maryland, USA) program was used for all forms of statistical analysis.

RESULTS

Hypolipidaemic drug treatment and its effect on the lipid profile

Details of these findings have been published previously.⁹ Briefly, in the structured care group all patients ($n = 800$) received atorvastatin. After dose titration, the patients on atorvastatin received the following dosages: 4% (31 patients), 10 mg/day; 82% (657), 20 mg/day; 11% (87), 40 mg/day; and 3% (25), 80 mg/day. The mean dose was 24 mg/day. During the study, 17 patients on atorvastatin dropped out because of side effects or personal reasons. In the structured care group, 95% of patients ($n = 759$) had mean LDL-C values < 2.6 mmol/litre (1000 mg/litre) after the titration period (mean change, -46%). The mean reduction in TGs was 31%, and in non-HDL-C 44% ($p < 0.0001$ v baseline and on study values of usual care for both). The mean increase in HDL-C was 7% ($p < 0.001$ v baseline and $p = 0.028$ v on study values of the usual care group). The LDL-C to HDL-C ratio was reduced by 50% ($p < 0.0001$ v baseline and usual care). In the usual care group, only 26% ($n = 211$) of the patients received hypolipidaemic drug treatment. Some patients ($n = 98$; 12%) discontinued these drugs after a six to eight month period. Thus, only a small proportion of the usual care patients received longterm hypolipidaemic drug treatment (14%; $n = 113$), mainly with statins (12%; $n = 97$) or fibrates (2%; $n = 16$). Only 3% of usual care patients ($n = 24$) attained the NCEP LDL-C treatment goal.

Endpoints

During the three year duration of the study, 292 CHD related events were recorded in 1600 patients: 196 (24.5%) patients on usual care had a CHD recurrent event or died compared with 96 (12%) patients on atorvastatin (risk ratio, 0.49; confidence interval (CI), 0.27 to 0.73; $p < 0.0001$).⁹ In detail, compared with usual care, structured care reduced total mortality by 43% ($p = 0.0021$), coronary mortality by 47% ($p = 0.0017$), coronary morbidity by 54% ($p < 0.0001$), and stroke by 47% ($p = 0.034$).

Renal function at baseline

In the kidney disease outcomes and quality initiative (K/DOQI) guidelines,¹⁵ chronic kidney disease is defined according to the presence or absence of kidney damage and degree of kidney function, irrespective of diagnosis. Among individuals with chronic kidney disease, five stages are described based on the degree of function indicated by glomerular filtration rate (GFR). In this classification scheme, stage one is associated with kidney damage with a normal GFR (≥ 90 ml/min), stage two with kidney damage and mildly decreased GFR (60–89 ml/min), stage three with moderately decreased GFR (30–59 ml/min), stage four with severely decreased GFR (15–29 ml/min), and stage five or kidney failure with a GFR less than 15. According to K/DOQI, 642 patients had a stage one, 864 a stage two, and 94 a stage three renal function status. Patients from each renal function status were similarly distributed in the two treatment groups.

Effect of dyslipidaemia and statin treatment on CrCl (treatment based analysis)

No statin treatment

In the usual care group, 687 patients were not on longterm hypolipidaemic drug treatment. These patients showed a mean reduction in CrCl of 5.3% ($p < 0.0001$; table 1; fig 1). At baseline, there were no significant differences in CHD risk factors between these patients and those in the structured care group on atorvastatin. Similarly, 17 patients in the structured care group who discontinued atorvastatin, for various reasons, had a decrease in CrCl of 4.9% ($p = 0.02$; table 1; fig 1).

Table 1 Creatinine clearance in the two treatment groups at baseline and at 48 months according to hypolipidaemic drug treatment (treatment based analysis)

	Baseline	48th month	p Value
Usual care, no statins (n=703)	77 (10)	72 (12) -5.3%	<0.0001
Usual care, on statins (n=97)	78 (12)	82 (8) +4.9%	0.003
Structured care, no atorvastatin (n=17)	76 (9)	73 (9) -4.9%	0.02
Structured care, on atorvastatin (n=783)	76 (13)	84 (3) +12%	<0.0001

Values are mean (SD) in ml/min.

Statin treatment

In the usual care group, simvastatin was used in 41 patients (5%; mean dose, 20 mg/day) and induced a mean 5.2% increase in CrCl ($p = 0.002$); atorvastatin was used in 25 patients (3%, mean dose, 15 mg/day) and increased CrCl by 8.1% ($p = 0.0003$); pravastatin was used in 23 patients (3%; mean dose, 24 mg/day) and fluvastatin in eight patients (1%; mean dose, 40 mg/day), with no significant increases in CrCl (2.4% and 1.8%, respectively). The overall effect on CrCl in statin treated patients ($n = 96$) was a 5% increase in CrCl ($p = 0.003$; table 1; fig 1). In the structured care group, 783 patients were on longterm atorvastatin treatment (mean dose, 24 mg/day) and showed a mean increase in CrCl of 12% ($p < 0.0001$; table 1; fig 1). This increase was dependent on baseline CrCl values. Figure 2 shows the increase in CrCl by baseline CrCl quartiles (intention to treat analysis). Patients with a GFR < 77 ml/min had a mean increase in CrCl of 15.4%, whereas those with a GFR > 77 ml/min had a mean increase in CrCl of 3.1%. Thus, the greatest benefit was seen in those with early renal dysfunction. Patients on higher atorvastatin doses (40–80 mg/day; $n = 112$) showed a greater increase in CrCl than those on lower doses (10–20 mg/day; $n = 688$): 13.8% v 10.9%, respectively ($p = 0.001$). In multivariate analysis, statin treatment showed a hazards ratio (HR) of 0.51 (95% CI, 0.39 to 0.66; $p < 0.0001$; table 2).

Changes in CrCl values in the structured and usual care groups (intention to treat analysis)

The following CrCl values were recorded in the two treatment groups at baseline and during the study.

Figure 1 Percentage change over time (up to 48 months) in creatinine clearance (CrCl) in the structured and usual care groups, according to hypolipidaemic drug treatment (treatment based analysis). m, months; w, weeks; *time at which the difference became significant ($p < 0.05$) compared with baseline. **Figure 2** Percentage change over time (up to 48 months) in creatinine clearance (CrCl) in the structured and usual care groups, by baseline CrCl quartiles (intention to treat analysis). m, month; Q, quartile; Q1, highest Q; Q4, lowest Q; SC, structured care; UC, usual care; w, week; *time at which difference became significant ($p < 0.05$) compared with baseline.**Table 2** Multivariate Cox predictive model for all CHD related events involving backward stepwise logistic regression

Variables	HR (95% CI)	p Value
Age (years)	1.07 (1.02 to 1.11)	0.02
Statin treatment	0.51 (0.39 to 0.66)	<0.0001
On treatment LDL-C < 2.6 mmol/l	0.67 (0.49 to 0.84)	<0.0001
On treatment LDL-C > 3.6 mmol/l	1.32 (1.13 to 1.56)	<0.0001
On treatment HDL-C > 1.0 mmol/l	0.87 (0.79 to 0.94)	0.002
On treatment HDL-C < 1.0 mmol/l	1.12 (1.04 to 1.28)	0.005
CrCl (with every 5% increase)	0.84 (0.73 to 0.95)	0.003
CrCl (with every 5% reduction)	1.10 (1.03 to 1.21)	0.01
Use of β blockers during study	0.72 (0.58 to 0.89)	<0.0001
Use of ACE inhibitors during study	0.84 (0.69 to 0.96)	0.01

Nineteen univariate predictors of all CHD related events all with $p < 0.10$ (the above plus: male sex, female sex, current smoking, family history of premature CAD, history of hypertension, history of diabetes mellitus, previous revascularisation, acute coronary syndrome, and previous myocardial infarction) were initially entered ($n = 1600$, 292 events). ACE, angiotensin converting enzyme; CAD, coronary artery disease; CHD, coronary heart disease; CI, confidence interval; CrCl, creatinine clearance; HDL-C, high density lipoprotein cholesterol; HR, hazards ratio; LDL-C, low density lipoprotein cholesterol.

Table 3 Creatinine clearance values in the two treatment groups at baseline and at 48 months (intention to treat analysis)

	Structured care (n = 800)			Usual care (n = 800)		
	Baseline	48th month	p Value	Baseline	48th month	p Value
Q1 (n = 200)	95 (11)	96 (13)	NS	96 (10)	95 (10)	NS
Q2 (n = 200)	77 (3)	80 (5)	0.002	78 (4)	76 (5)	0.03

All (n = 800)	76 (13)	84 (8)	<0.0001	77 (12)	74 (11)	0.008

Values are mean (SD) in ml/min.

Q, quartile.

Usual care group

The mean (SD) baseline CrCl was 77 (12) ml/min and this was reduced by the end of the study to 74 (11) ml/min (4.4%; $p = 0.002$). Table 3 and fig 2 show the CrCl values by quartiles and their changes during the study are reported.

Structured care group

The mean (SD) baseline CrCl was 76 (13) $\mu\text{mol/litre}$. This was increased by the end of the study to 84 (8) $\mu\text{mol/litre}$ (11.6%; $p < 0.0001$). Table 3 and fig 2 show the CrCl values by quartiles and their changes during the study.

Relation between CrCl values and clinical outcome

In all patients, multivariate analysis of CHD related events revealed an HR of 1.10 (95% CI, 1.03 to 1.21; $p = 0.01$) with each 5% reduction in CrCl (table 2) and an HR 1.18 (95% CI, 1.09 to 1.29; $p < 0.001$) with each 10% reduction in CrCl. In contrast, multivariate analysis of CHD related events revealed an HR of 0.84 (95% CI, 0.73 to 0.95; $p = 0.003$) with each 5% increase in CrCl (table 2) and an HR of 0.73 (95% CI, 0.64 to 0.82; $p < 0.001$) with each 10% increase in CrCl.

The role of blood pressure and HDL-C

Both systolic blood pressure and diastolic blood pressure were similar at baseline and during the study in the structured and usual care patients, and among all quartiles of baseline CrCl in both treatment groups (table 4). The effect of statin treatment on blood pressure could not be assessed because patients were also on other blood pressure lowering drugs (β blockers, angiotensin converting enzyme (ACE) inhibitors, calcium channel blockers, diuretics, and nitrates).⁹ There were no significant differences in LDL-C and TG values between the CrCl quartiles. There was a lower HDL-C mean value in the low baseline CrCl quartiles of both the structured (ANOVA, $p = 0.002$) and usual care groups (ANOVA, $p = 0.0001$). These differences remained significant during the study in the usual care group, but significance was abolished in the structured care group.

Other factors that may have influenced clinical outcome

There were no significant differences between the structured and usual care groups in demographic characteristics and CHD factors at baseline and in concomitant drug treatment (particularly in ACE inhibitors or calcium channel blockers, which might influence GFR; table 5) and degree of glycaemic control or blood pressure during the study.⁹ Both at entry and during the study, smokers were similarly distributed in the two treatment groups (4.5% and 3.6% in the usual care and structured care groups, respectively). Only five patients in the usual care group and three in the structured care group were on a low protein diet. Similar numbers of patients lost > 10% of their body weight in the two treatment groups (39 in the usual care and 45 in the structured care groups). Nevertheless, every measurement of SCr was adjusted for

body weight and the Cockcroft-Gault formula, used to calculate GFR from SCr, corrects for age, sex, and body weight. Thus, it is not possible that we had false low or false high GFR values. Moreover, results were fully adjusted for 26 predictors of CHD related events (table 3). Thus, the beneficial effect on clinical outcome should mainly be attributable to statin treatment. There were no extreme values of SCr at baseline (that is, extremely high values) because the patients were excluded from the study if they had a SCr value > 13 mg/litre; 115 $\mu\text{mol/litre}$. The method used to assess SCr has high reproducibility, and the use of mean values of a large number of patients (800 in each treatment group), together with the different effects on SCr in each group, reduced to a minimum any regression to the mean effect. All patients in both treatment groups received advice on life style changes and the body mass index (a rough index of compliance with life style measures) was similar in both groups.⁹

DISCUSSION

The present study suggests that renal function declines, as shown by the significant decrease in CrCl values, over a period of three years in dyslipidaemic patients with CHD and normal renal function at baseline who are not treated with a statin. Moreover, statin treatment not only inhibits this deterioration in renal function, but it significantly increases CrCl in these patients. The greatest benefit is seen in those with early renal dysfunction.

In the Helsinki heart study,⁶ there was an average 3% increase in SCr during the five year period of the study (both in the placebo and gemfibrozil subgroups). This was a primary prevention study, and therefore the decline of renal function may have been slower. Dyslipidaemia and hypertension accelerated this change.⁶ Subjects with an LDL-C to HDL-C ratio > 4.4 had a 20% faster decline than those with a ratio < 3.2. Both the contribution of the lipoprotein ratio and the protective effect of HDL-C alone remained significant in multiple regression analyses. Our patients had a mean LDL-C to HDL-C ratio value of 4.6, which was reduced by 50% (to 2.3), HDL-C was increased by 7% with atorvastatin, and 40% of patients had arterial hypertension, which was also effectively treated in most of the patients.⁹ Thus, effective treatment of two risk factors for renal function deterioration might explain the reduction in SCr and the consequent CrCl increase. Nevertheless, efficient treatment of hypertension over a three year period could explain the stabilisation of the CrCl values, but probably not its significant increase. This interpretation is supported by several findings of the study. First, 17 patients from the structured care group who discontinued atorvastatin, for various reasons, and those on usual care not on statins ($n = 687$) had a significant reduction (compared with baseline) in CrCl of 4.9% and 5.3%, respectively, by the end of the study (fig 1), despite having similar systolic and diastolic blood pressure values to those of statin treated patients (table 4). Second, the CrCl increase was seen

in structured care patients with low baseline CrCl (fig 2), despite the fact that they had similar systolic and diastolic blood pressure values to those with a high baseline CrCl (tables 2 and 3). Third, the reduction in CrCl was more prominent in usual care patients with low baseline CrCl (fig 2), despite the fact that they had similar systolic and diastolic blood pressure values to those with high baseline CrCl (table 4). Furthermore, it has been shown in the Losartan intervention for endpoint reduction in hypertension trial¹⁶ that during the study SCr increased by 13% in both treatment groups, despite effective control of blood pressure. Moreover, in spontaneously hypertensive rats, statins reduce hypertension related renal damage and proteinuria, independently of cholesterol or blood pressure values.¹⁷

“The early increase in creatinine clearance in the structured care group is probably related to an effect of statin treatment on endothelial related vasodilatation”

In the structured care group, the lower the baseline CrCl value (even within the normal range), the greater the post-statin increase (fig 2). Data suggest that this was a direct effect of atorvastatin on renal function, because the increase in CrCl was manifested as early as the sixth week of treatment. Moreover, in the patients who discontinued atorvastatin treatment (personal reasons or side effects), the CrCl returned to previous values within four weeks, even though other treatments were continued. The increase in CrCl values gradually became higher after the sixth week of treatment. There are three possible explanations for this. First, the effect of atorvastatin may be dose dependent. Our results suggest that higher doses of atorvastatin increase CrCl more than

lower doses. By the sixth week of treatment, all patients (n = 800) were on a 10 mg/day dose, whereas after titration most patients (n = 657) were on 20 mg/day, and some (n = 112) were on 40 or 80 mg/day. Second, a gradual improvement of the lipid profile during the titration period, as the atorvastatin doses increased, might be another possible explanation. Third, patients on structured care had fewer CHD recurrent events during the study, thus preserving cardiac performance and renal blood flow.

The early increase in CrCl in the structured care group is probably related to an effect of statin treatment on endothelial related vasodilatation. It is well known that statins exert a beneficial effect on endothelial vasomotor function.^{18–19} In fact, better perfusion of the myocardium and improved coronary blood flow have been documented soon after starting statin treatment.^{18–21} Therefore, better renal blood flow is a possibility. Regression of atheromatous renal artery stenosis, regression of intimal hyperplasia in arcuate arteries, or reversal of hyaline arteriosclerosis in afferent arterioles are unlikely to be achieved as early as the sixth week of treatment. However, such effects might be involved in the further gradual increase of CrCl during the three year study period. It has also been suggested that dyslipidaemia per se is a significant aggravating factor for renal dysfunction in patients with diabetes²² and hypertension⁶; in the GREACE trial, 20% of our patients had diabetes and 40% had arterial hypertension. High serum cholesterol seems to have a similar action on glomerular mesangial cells and endothelial cells.²² This appears to be analogous to the process of atherosclerosis, because mesangial cells have binding sites for LDL and oxidised LDL, help recruit macrophages, and secrete proliferative factors. Clinical and experimental studies have demonstrated the role of lipids and lipoproteins in the

Table 5 Medical treatment during the study (for at least six months)

ACEI, angiotensin converting enzyme inhibitors; ARBS, angiotensin II receptor blockers.

decline of renal function, with an emphasis on glomerulosclerosis.^{23–26} Statins have been shown to have a protective effect on renal function, by diminishing the lipid contribution to glomerulosclerosis,²⁷ reducing neutrophil and macrophage infiltration,²⁷ and upregulating the cytokine interleukin 6^{28–29} or endothelial nitric oxide synthase.³⁰ In this setting, several animal studies have been reported in which the rate of decline of GFR and/or renal morphology is beneficially modified after the alteration of the lipoprotein profile by dietary or pharmacological manipulation, including statins.^{2–31–32} Thus, the possibility that both the pleiotropic effects of atorvastatin and the improved lipid profile contributed to this effect cannot be excluded.

It is plausible that the fall in SCr values, as opposed to a decrease in the expected rise seen in the HPS trial,^{7–33} may only be seen when a considerable reduction in LDL-C is achieved.^{34–35} In the GREACE trial,⁹ the mean fall in LDL-C was 2.0 mmol/litre, whereas in the HPS trial³³ this was only 1.0 mmol/litre. Moreover, the baseline non-HDL-C value, a significant determinant of deterioration of renal function,¹ was very high in the GREACE patients (mean, 5.6 mmol/litre; SD, 0.9) and this was reduced in the structured care group by 2.4 mmol/litre (–44%; $p < 0.0001$).⁹ In the HPS study, the baseline non-HDL-C value was 4.8 mmol/litre and was reduced by 1.2 mmol/litre by simvastatin.³³ The baseline HDL-C value, another significant determinant of deterioration of renal function,¹ was low in both treatment groups of GREACE (1.0 mmol/litre). In the structured care group, the HDL-C values were significantly increased to 1.1 mmol/litre (7%; $p < 0.001$) during the study. This increase was analogous to that reported by the HPS in simvastatin allocated patients. Thus, differences between the effect of statin treatment on renal function in HPS and GREACE could be mainly attributed to the greater reduction in LDL-C and non-HDL-C values seen in GREACE, because the effect of statin treatment on HDL-C concentrations was similar in both studies.

In the usual care group, 12% of patients were on longterm statin treatment ($n = 97$). Usual care patients on statins also had an increase in CrCl, but to a lesser extent than that seen in structured care patients (4.9% *v* 12%; $p = 0.0003$). There could be several reasons for this difference. The increase in CrCl might be more evident with certain statins, and/or the doses of other statins were low and their effect on the lipid profile was limited.

We recently reported³⁶ that 26 of 115 primary prevention patients who showed a drop in serum urate also had a 3% reduction ($p = 0.05$) in SCr concentrations during short term atorvastatin treatment. In GREACE, there was also a significant reduction in urate in atorvastatin treated patients, which correlated with the decrease in SCr ($r = 0.82$; $p < 0.0001$; data not shown). One fibrate (fenofibrate) can reduce urate concentrations, by reducing its tubular reabsorption. However, all fibrates, with the exception of gemfibrozil, increase serum creatinine values⁷ through mechanisms that have not yet been clarified. It is highly unlikely that the increase in CrCl in GREACE is associated with intrarenal alterations in tubular function, given that, unlike urate, SCr is not subject to reabsorption in the renal tubules. Increased SCr excretion is probably mediated through the improvement in CrCl, to which we also attributed the reduction in urate. Thus, statins and fibrates probably have completely different ways of affecting serum creatinine and urate concentrations. In two other studies,^{37–38} involving patients with peripheral arterial disease, atorvastatin (20 mg/day; $n = 25$; $p = 0.007$) and simvastatin (20 mg/day; $n = 103$; $p = 0.007$) also decreased SCr by about 3%. In both these studies,^{37–38} and in the GREACE trial,⁹ the decrease in SCr was greater in those with baseline SCr values at the higher end of the reference range.

A low CrCl (and high SCr) could represent a continuous CHD risk factor even within normal limits. Probably “the lower the better” applies to SCr values, as it does to LDL-C and systolic blood pressure. This hypothesis is supported by the findings of a recent observational study.³⁹ This study showed that higher SCr concentrations, mostly within the normal range (mean on study quartile values 84, 94, 104, and 120 $\mu\text{mol/litre}$), were a strong and independent predictor of CHD adverse outcomes and stroke after first myocardial infarction, in 2677 patients during a mean follow up period of 3.4 years; most of our patients had suffered a recent myocardial infarction.

“Statins and fibrates probably have completely different ways of affecting serum creatinine and urate concentrations”

There are several limitations to our study. The potential effect of atorvastatin on renal function will need to be investigated extensively using more specific tests (for example, urine collections for CrCl and the use of isotopes or markers such as inulin or ⁵¹Cr-EDTA clearance). The GREACE study was not double blind and placebo controlled because of ethical and practical issues. This unsponsored target based study could not be designed in any other way, because its main goal was to assess the clinical benefit from NCEP guideline implementation in comparison with that seen with real life treatment patterns. Only a few patients on statins other than atorvastatin were evaluated. Urine analyses were not performed to assess microalbuminuria, an alternative marker for kidney disease. Proteinuria was assessed at baseline and at the end of the study, and we found no evidence that the statins used in the study induced or exacerbated preexisting proteinuria. In addition, there are no reported cases in the literature showing that atorvastatin induces proteinuria, whereas there are studies suggesting that it reduces it significantly,³⁴ even over and above the reduction induced by ACE inhibitors or angiotensin receptor blockers.⁴⁰ Moreover, in the GREACE diabetes substudy,⁴¹ there was no evidence of an increased risk of developing proteinuria in the safety data of the patients with diabetes on atorvastatin for three years, in accordance with previous observations.⁴² However, this is a small group of patients ($n = 161$). A recent study involving 100 patients with familial hypercholesterolaemia and normal glucose tolerance, treated with 10 to 40 mg/day of atorvastatin, showed a significant reduction in microalbuminuria and a significant increase in CrCl.⁴³ In addition, to date no other statin trial has included the measurement of proteinuria. Undoubtedly, the results of the GREACE trial (fall in SCr) together with the rosuvastatin findings (complication mentioned in the rosuvastatin data sheet) will lead to a greater awareness about renal function, proteinuria, and statins.

CONCLUSIONS

In dyslipidaemic patients with CHD who have normal baseline renal function, there is a decline in CrCl over time, which further increases the risk for clinical events related to arteriosclerotic cardiovascular disease.

In contrast, patients on longterm aggressive statin treatment experience a significant increase in CrCl, which contributes to the reduction of risk for clinical events. Prevention of an additional CHD risk factor, such as renal insufficiency, might prove to be beneficial for patients with established CHD. Renal and coronary artery disease may progress in parallel. Similar treatments (for example, statins) may be beneficial to both the heart and kidneys.

Take home messages

- Patients with dyslipidaemia and coronary heart disease (CHD) who have normal baseline renal function show a decline in creatinine clearance over time, which further increases the risk for CHD related clinical events
- Longterm aggressive statin treatment significantly increases creatinine clearance, contributing to the reduction of risk for clinical events
- This beneficial effect is greatest in those with early renal dysfunction
- Prevention of an additional CHD risk factor, such as renal insufficiency, might be beneficial for patients with established CHD
- Statins may be beneficial to both the heart and the kidneys
