SHORT REPORT

Extremely high maternal alkaline phosphatase serum concentration with syncytiotrophoblastic origin

J Clin Pathol 2005;58:72–76. doi: 10.1136/jcp.2003.015362

An extremely high alkaline phosphatase (AP) concentration (3609 IU/litre) was found in a 20 year old primigravida at 37 week's gestation, prompting an examination of its histological and cellular origin. Immunohistochemistry and western blots using antibodies against AP, Ki-67, phospho-protein kinase B (Akt), phospho-p44/42 mitogen activated protein kinase/extracellular signal regulated kinase 1/2 (MAPK/Erk1/2), phospho-glycogen synthase kinase-3 β (GSK-3 β), phospho-stress activated protein kinase/c-Jun N-terminal kinase, total-Akt, total-GSK-3 β , and phospho-p38-MAPK were carried out on index and control placental samples of the same gestational age. Compared with controls, staining of the index placenta showed minimal AP labelling of the brush border and remarkable positivity of the intervillous space. Cytotrophoblastic proliferation was 8–10% in the index placenta compared with 1–2% in controls. The index placenta also had raised concentrations of protein kinases with important roles in cell differentiation. The proliferation and differentiation rates of the cytotrophoblasts were found to be five times higher in index samples than in controls. It is hypothesised that loss of syncytial membranes in immature villi led to increased AP concentrations in the maternal circulation and decreased AP staining of the placenta. Loss of the syncytium might also stimulate increased proliferation of villous cytotrophoblasts, which would then fuse and maintain the syncytium.

Alkaline phosphatase (AP) is known to be produced by the liver, bones, small intestine, and kidneys, and different AP isoforms are also expressed by the placenta during pregnancy.¹ The average amount of AP in one human term placenta amounts to 40 mg.² The placental isoforms are known as heat stable AP, because they are heat resistant at 60°C, a property that is the main criterion for distinguishing them from the other isoenzymes.³ In early pregnancy, the tissue non-specific AP isoenzyme is mainly expressed in the placenta, and reaches a peak value around 10 weeks of pregnancy. At the end of the second trimester, most of the AP activity comprises term placental AP isoenzymes¹ (90% of which are the P1 type, 10% the P2 type) produced by the syncytiotrophoblasts, and these isoenzymes appear in maternal serum between the 15th and 26th weeks of pregnancy.⁴ Their plasma concentrations increase exponentially during gestation—they are present at concentrations three times greater than those seen in non-pregnant women—and have a long half life (seven days) postpartum.⁵ Extremely high AP concentrations should arouse a suspicion of bone, hepatic, endocrine, and renal diseases, malignancy, and drug treatment, but can also be associated with heavy smoking and pregnancy (table 1).^{3, 4, 6}

The aetiology of increased AP is still unknown, and because we could find no literature dealing with its cellular background we decided to investigate the biochemical and pathophysiological aspects of this phenomenon.

“Extremely high alkaline phosphatase concentrations should arouse a suspicion of bone, hepatic, endocrine, and renal diseases, malignancy, and drug treatment, but can also be associated with heavy smoking and pregnancy”

METHODS

Clinical data

A 20 year old primigravida was admitted to the clinic because of oedema and suspicion of pre-eclampsia during the 37th gestational week. After a general examination and precise observation, an extremely high serum AP concentration was detected (3609 U/litre). Blood pressure was normal, there was no proteinuria, and the patient had no complaints. Laboratory tests showed that her blood parameters and renal, hepatic, and endocrine functions were normal. No systemic immune disease was detected. Ovarian tumour markers (CA-125, carcinoembryonic antigen, and CA-19-9) were non-pathological. The bone associated AP fraction was determined to be only 97 U/litre (normal range, 100–350). Electrophoresis of total AP using the Hydrigel Protein kit (Sebia, Issy-les-Moulineaux, France) showed the presence of 65.9% (2128 U/litre) P1 and 30.1% (972 U/litre) P2 placental isozymes. On the 38th week of pregnancy, a mature girl was born by vaginal labour with a weight of 3200 g and an Apgar score of 9/10. The 730 g placenta had no macroscopic abnormalities or infarction. The human chorionic gonadotrophin concentration declined quickly after birth, whereas the concentration of AP decreased exponentially during the following weeks and reached normal values at 12 weeks postpartum (fig 1).

Histopathology and immunohistochemistry

Samples were obtained from the index case and from normal term placentas (n = 5). Tissue blocks were routinely fixed in formalin and embedded in paraffin wax. Full thickness representative blocks were taken from three different central-paracentral areas of each placenta and an en face block of the maternal surface was cut. Further blocks from the umbilical cord and membranes were sampled for routine examination

only. Consecutive serial sections (4 µm thick) of the same blocks were also cut and prepared for immunostaining. Tissue samples were stained with haematoxylin and eosin for histopathological examination, or with monoclonal IgG antibodies against cell proliferation marker Ki-67 (Histo-pathology, Pecs, Hungary) and placental AP (Lab Vision, Fremont, California, USA) for immunohistochemical evaluation. Immunostaining was performed by the streptavidin-biotin-immunoperoxidase technique, with H₂O₂/3-amino-9-ethylcarbazole development using the Universal kit (Immunotech, Marseille, France). Index and control placen-tas were examined blindly according to a standard protocol by two of the authors (BH and AB) independently.

Figure 1 Changes in total serum alkaline phosphatase (AP) concentrations during pregnancy and postpartum. The AP concentration reached its peak at the 37th gestational week. After birth, it decreased exponentially during the following weeks, and became normal 12 weeks later.

SDS-PAGE and chemiluminescent western blot analysis

Explants (100 mg each) were taken from five different areas of normal and index placental tissues, and were homogenised on ice in 10 ml of lysate buffer (pH 7.5, 50mM Tris, 1mM PMSF). Homogenates were centrifuged at 4000 ×g for five minutes, supernatants were collected, and their protein contents were measured using the BioRad assay and equalised in Laemmli sample buffer. Protein extracts (10 µg each) were loaded and separated by 12% sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE). Western blot analyses were performed by applying rabbit polyclonal IgGs to the following antigens: phospho-protein kinase B (phospho-Akt), phospho-p44/42 mitogen activated protein kinase/extracellular signal regulated kinase 1/2 (phospho-p44/42 MAPK/Erk1/2), phospho-glycogen synthase kinase-3β (phospho-GSK-3β), phospho-stress activated protein kinase/c-Jun N-terminal kinase (phospho-SAPK/JNK), total-Akt, and total-GSK-3, in addition to mouse monoclonal IgG to phospho-p38-MAPK (Cell Signaling Technology Inc, Beverly, Massachusetts, USA). Horseradish peroxidase labelled goat antirabbit and antimouse IgGs (Sigma-Aldrich Co, St Louis, Missouri, USA) were used as secondary antibodies. Protein bands were revealed by the ECL chemiluminescence system (Amersham Pharmacia Biotech, Little Chalfont, Buckinghamshire, UK). This was followed by quantitative densitometric analysis of the bands with Scion Image for Windows and ImageJ software.

RESULTS
Histopathology

In the index case, there were increased numbers of syncytial knots on the surface of the chorionic villi (fig 2A). Several groups of avascular tertiary villi with homogenous hyaline-like stroma were also found but fetal vessel thrombosis was not revealed. "Proliferation centres" were frequent in the

Figure 2 Histopathological and immunohistochemical examination of the index and control placentas. (A–C) Haematoxylin and eosin staining of placental tissue sections (original magnification, $\times 100$). (A) Normal term placenta, 38 weeks of gestation; (B) index placenta containing immature villi organised into proliferation centres and fibrotic, avascular villi (arrows); (C) villous crowding in the index placenta with pinched intervillous space (arrowheads) and syncytial knotting (arrows). (D, E) Immunohistochemical staining for alkaline phosphatase (AP) in placental tissue sections with inserts of higher magnification (original magnification, $\times 200$). (D) In normal placentas, intensive linear positivity of the brush border membrane was detected (arrow), whereas in the index placenta, weak, diffuse, interrupted granular positivity of the membrane was seen (the arrow shows a normal part, whereas the arrowhead points to AP staining of the intervillous space). (F, G) Immunohistochemical staining for Ki-67 in placental tissue sections (original magnification, $\times 100$). The nuclei of proliferating cytotrophoblasts were stained (one of the arrows shows a nucleus in the mitotic phase). (G) The ratio of proliferating cells in the index placenta was 8–10%, whereas it was approximately 1–2% in control placentas of the same gestational age (F). No Ki-67 staining was seen in either the syncytiotrophoblast layers or the villous stromal cells (arrowhead).

immature villi, unlike in other term placentas (fig 2B). Several areas showed villous crowding, where the intervillous space was nearly obliterated by the large, poorly vascularised villi (fig 2C). Histopathology also showed asymmetrical intimal fibrin cushions in the fetal chorionic vessels. The maternal vessels showed no specific changes. Control placentas showed none of the above listed lesions.

Immunohistochemistry

Similar to the data in the literature,³ in control placentas AP was normally found on the brush border membranes of the syncytiotrophoblast layer of the villus surface (fig 2D). No staining could be seen in other villous cells, such as cytotrophoblasts. Staining of the index placenta resulted in minimal AP labelling of the brush border, and yielded a remarkable diffuse AP positivity in the intervillous space (fig 2E). We used anti-Ki-67 IgG and counted 10 fields in every case to examine the average ratio of proliferating cells, which was found to be approximately 1–2% in control placentas (fig 2F), whereas the index placenta showed significantly increased positivity of the cytotrophoblastic cells underlying the syncytium so that the average ratio of proliferating cells was 8–10% (fig 2G).

SDS-PAGE and chemiluminescent western blot analysis

Five different proteins involved in cellular signal transduction pathways were investigated in the term placental tissue extracts. As shown in fig 3, compared with normal placentas, some markers showed remarkable overexpression in the index sample. Phospho-GSK-3 β (fig 3A) showed a similar increase to that of phospho-Akt (fig 3C), whereas there were no differences in total-GSK-3 (fig 3B) and total-Akt (fig 3D) expression. Three other basic signal transduction proteins—phospho-p38-MAPK (fig 3E), phospho-SAPK/JNK (fig 3F), and phosphorylated p44/42 MAPK/Erk1/2—were found to be overexpressed in the index placenta compared with controls (fig 3G). Densitometric analyses were performed, and the following differences in protein content were found in the index case compared with controls (100%): phospho-GSK 3 β , 152%; total-GSK-3, 106%; phospho-Akt, 174%; total-Akt, 103%; p38MAPK, 249%; phospho-p44/42 MAPK/Erk1/2, 561%; and phospho-SAPK/JNK, 202% (table 2).

DISCUSSION

Only a few publications could be found that dealt with isolated extreme rises in AP during pregnancy,^{8,9} although

Figure 3 Chemiluminescent western blot analyses of control (1) and index (2) placentas. (A, B) Expression of total glycogen synthase kinase-3 β (GSK-3 β) was the same in both samples (A1, A2), whereas significantly increased expression of phospho-GSK-3 β was found in the index placenta (B2) compared with the control placenta (B1). (C, D) The expression of total protein kinase B (Akt) was similar in both control and index placentas (C1, C2), whereas the expression of phospho-Akt was considerably higher in the index sample (D2) than in the normal placentas (D1). (E–G) Expression of (E) phospho-p38-mitogen activated protein kinase (MAPK), (F) stress activated protein kinase/c-Jun N-terminal kinase, and (G) p44/42 MAPK/extracellular regulated kinase 1/2 was greatly increased in the index placental tissue samples (E2, F2, G2) compared with controls (E1, F1, G1).

numerous diseases are known to be related to high AP concentrations (table 1).^{3–6} It has been reported¹⁰ that raised AP concentrations can predict premature birth in the second trimester, but this parameter has no clinical relevance because of its low sensitivity and specificity. Placental infarcts or abruption could also be the reason for increased AP concentrations in the maternal serum. In non-pregnant women with high AP, it is necessary to exclude malignancy. Fishman *et al* were the first to report on malignancy derived

placental-like alkaline phosphatase (PLAP) production.⁴ Increased concentrations of PLAP have been found in 15–64% of ovarian cancers, 54% of colorectal carcinomas, and 40% of lung cancers.^{6–11} PLAP activity was found to constitute less than 1% of total AP activity in non-pregnant, non-smoking women, and its connection to numerous malignant diseases has been shown.

With regard to our case, we could exclude liver, kidney, bone, and immunological diseases, in addition to thyroid dysfunction. Intrauterine growth retardation, pre-eclampsia, and Down's syndrome were also excluded. The mother did not smoke and was not undergoing drug treatment. Because the concentration of β human chorionic gonadotrophin was within the normal range at the time of hospitalisation (17 706 IU/ml; reference range, 94–60 000 IU/ml at the 29–40th week of pregnancy) and did not change appreciably, a syncytiotrophoblastic disorder was not suspected originally. To gain a better insight into the morphological and functional changes leading to this phenomenon, several types of pathological and biochemical examinations were carried out. Numerous cellular signal transduction pathways via well established protein kinases that might lead to proliferation were also investigated.

In our study, histopathological examination found several avascular villi in one block, intimal fibrin cushions in fetal vessels, and diffuse syncytial knot formation on villous surfaces. In several areas, proliferation of the cytotrophoblasts was detected and persistence of embryonal villi was present.

“When a raised serum alkaline phosphatase concentration is present during pregnancy, differential diagnostically important diseases must be systematically excluded”

Immunohistochemical and western blot results also pointed to an increased rate of cytotrophoblast proliferation. Numbers of Ki-67 positive proliferating cytotrophoblastic cells were found to be five times greater in the index sample than in the controls. A remarkable increase in phosphorylated p44/42 MAPK/Erk1/2, known to be a signal transduction factor involved in proliferation and differentiation, was detected, indicating an increased tendency for cell differentiation and syncytiotrophoblast formation. Increases in other protein kinases, p38MAPK and SAPK/JNK, also known to take part in the signal transduction necessary for cell activation were detected. Increased amounts of phospho-Akt (active form) and phospho-GSK-3 β (inactive form), together with a slight difference between the total-Akt and total-GSK-3 β concentrations, suggested a possible inhibition of the apoptotic pathway. As published previously, Akt is known to regulate cellular processes in response to phosphatidylinositol-3 kinase activation. Phospho-Akt transduces signals to

Table 2 Comparison of immunohistochemistry and western blot results in the index and control placentas		
Method	Index placenta	Control placentas
Immunohistochemistry	Slight and discontinuous AP staining in syncytiotrophoblast brush border membrane 8–10% Ki-67 positive syncytiotrophoblast cells/field on average	Intensive continuous AP staining in syncytiotrophoblast brush-border membrane 1–2% Ki-67 positive syncytiotrophoblast cells/field on average
Western blot	Total-Akt 103% Total-GSK-3 β 106% Phospho-Akt 174% Phospho-GSK-3 β 152% Phospho-Erk 1/2 561% Phospho-SAPK/JNK 202% p38MAPK 249%	Total-Akt 100% Total-GSK-3 β 100% Phospho-Akt 100% Phospho-GSK-3 β 100% Phospho-Erk 1/2 100% Phospho-SAPK/JNK 100% p38MAPK 100%

Take home messages

- We report a patient with an extremely high serum alkaline phosphatase (AP) concentration at 37 week's gestation
- Compared with controls, staining of the index placenta showed minimal AP labelling of the brush border and remarkable positivity of the intervillous spaces
- Cytotrophoblastic proliferation was greater in the index placenta than in the controls, and the index placenta also had raised concentrations of protein kinases with important roles in cell differentiation
- The proliferation and differentiation rates of the cytotrophoblasts were found to be five times higher in the index samples than in the controls
- We suggest that loss of syncytial membranes in immature villi led to increased AP concentrations in the maternal circulation and decreased AP staining of the placenta
- Loss of the syncytium might also have stimulated increased proliferation of the villous cytotrophoblasts, which would then fuse and maintain the syncytium

activate cell growth, survival, proliferation, and differentiation, at the same time inhibiting proapoptotic signals via phosphorylation and thus inactivation of GSK-3 β .¹² Summarising our observations, we suggest that changes in the expression of phosphorylated p44/42 MAPK/Erk1/2 taken together with the immunohistochemical findings of increased Ki-67 expression indicate an intensive cytotrophoblastic proliferation. The inhibition of apoptosis is mediated by at least two pathways. Phospho-Akt inactivates GSK-3 β , a proapoptotic factor, whereas p38MAPK, an important factor for cell survival, might also indicate the activation of an alternative antiapoptotic process. According to the data in the literature, the cell activating effect of p38MAPK is mediated via several transcription factors (Stat-1, Atf-2, etc), similar to the JNK/JUN pathway.¹³

In control placentas, we detected strong AP labelling of the brush border membrane of the syncytiotrophoblasts, whereas minimal AP staining of the brush border was found in the immature villi of the index placenta, and a remarkable diffuse AP positivity was seen in the intervillous spaces. We hypothesise that loss of the syncytial membranes in immature villi led to increased AP concentrations in the maternal circulation and decreased AP staining of the placenta. Loss of the syncytium might also have stimulated increased proliferation of the villous cytotrophoblasts, which would then fuse and maintain the syncytium.

Although cytotrophoblast proliferation and the increased AP concentration did not affect fetal development in our present case, attention should be drawn to the pathophysiology of this phenomenon. Our investigations shed new light on a significant change in placental function, the exact cause

of which is still to be elucidated. In conclusion, when a raised serum AP concentration is present during pregnancy, differential diagnostically important diseases must be systematically excluded. In such cases, we would also recommend precise monitoring of fetal and maternal conditions, histopathological examination of the placenta, and more attention to the follow up of declining AP concentrations after delivery.
