Accepted for publication 29 March 2005

Background: Several studies suggest that melanoma may be resistant to treatment because of resistance to apoptosis and that this may be the result of activation of the extracellular signal regulated kinase (ERK1/2) pathway.

Aims: To test this hypothesis by examining the expression of ERK1/2 and its activated form in histological sections of melanoma and its relation to known prognostic features of the disease.

Materials/Methods: Immunohistochemistry with antibodies to ERK1/2 and phosphorylated ERK (p-ERK) was performed on formalin fixed sections from 42 primary melanomas, 38 metastases, and 20 naevi. Fourteen of the primary melanomas were in the radial and 28 in the vertical growth phase.

Results: ERK1/2 was widely expressed (100%) in all the (pigmented) lesions studied. p-ERK1/2 expression was much lower in compound (32.4%) and dysplastic (54.5%) naevi than in primary melanoma (nodular 78.8%, superficial spreading 67%) and subcutaneous metastases (76.3%). p-ERK expression was much lower in lymph node metastases (48.5%), suggesting that the microenvironment may influence the activation of ERK. There was a (non-significant) trend for p-ERK expression to be higher in thick (>1.0 mm) versus thin (≤1.0 mm) melanoma (p=0.23). There was a trend for overall survival to be related to p-ERK expression in patients with melanoma over 1 mm in thickness.

Conclusions: Expression of activated ERK1/2 in melanocytic lesions appears to be related to malignant potential so that activation of ERK1/2 may be important in melanoma progression. These results provide important histological support for the proposal that inhibition of this signalling pathway may be useful in treatment of melanoma.

Cutaneous melanoma is a malignant neoplasm of melanocytes and is an important cause of morbidity and mortality in Western countries that have predominantly white populations.^{1,2} It ranks as the third most common form of skin cancer in white skinned people, after basal cell carcinoma and squamous cell carcinoma, and continues to increase in incidence despite ongoing public health campaigns in many countries. In a proportion of patients melanoma appears to arise in association with naevi, particularly dysplastic or atypical naevi, indicating that naevi can be premalignant lesions.

"It is generally believed that chemotherapy kills cancer cells by induction of a final common pathway that leads to programmed cell death or apoptosis"

Various features of primary melanoma, including clinical characteristics such as the anatomic site of the tumour, patient age and sex, and pathological features of the primary tumour, such as its Breslow thickness, Clark's level, ulceration, dermal mitotic rate, satellite deposits, lymphocytic infiltration, and histological type, have been studied to determine their prognostic relevance.^{3,4} The prognosis of thin melanoma is good⁵ and surgical resection in early stages is usually curative. However, once melanoma has spread beyond the skin and regional lymph nodes, it is frequently incurable by currently available chemotherapeutic and other agents.⁶ Although different forms of chemotherapy have several biochemical targets, it is generally believed that chemotherapy kills cancer cells by induction of a final common pathway that leads to programmed cell death or apoptosis characterised morphologically by cell shrinkage,

chromatin condensation, and extensive nuclear and cellular fragmentation.^{7,8}

One of the basic properties of cancer cells is thought to be their resistance to apoptosis, leading to their prolonged survival.^{9,10} Traditionally, two principal pathways to apoptosis are recognised: the transmembrane "extrinsic" pathway and the mitochondrial "intrinsic" pathway. Both are dependent on the activation of caspases and both are subjected to regulation by proapoptotic and antiapoptotic proteins of the Bcl-2 and inhibitor of apoptosis families.^{11–13} In previous studies on melanoma cell lines, we found that a common cause of resistance to apoptosis was activation of the mitogen activated protein kinase (MAPK) family and, in particular, extracellular signal regulated kinase 1/2 (ERK1/2).¹⁴ Similar results were found in studies on other cancers.^{15,16} Activation of MAPK (ERK1/2) was detected more frequently in primary melanoma than in naevi,¹⁷ and introduction of activated MAPK kinase into melanocytes resulted in tumorigenesis in nude mice.¹⁸ In addition to inhibition of apoptosis, the ERK1/2 pathway also plays an important role in the regulation of cell division, as discussed elsewhere.^{19,20}

In view of the potential importance of this signalling pathway as a cause of resistance to apoptosis and tumour progression, we investigated its importance in melanoma by immunohistological examination of its expression and activation to test the hypothesis that these features may be related to known prognostic features of melanoma, such as thickness and mitotic rate. The results support previous

Table 1 Summary of the patient demographics and melanocytic lesions

Melanocytic lesions	N	Median age	Sex	
			Male	Female
Compound naevus	10	36.5	6	4
Dysplastic naevus	10	36.5	7	3
Melanoma ≤ 1.0 mm	18	67.5	7	11
Melanoma > 1.0 mm	24	69.5	21	3
Subcutaneous metastasis	21	74	12	9
Lymph node metastasis	17	60	9	8
Total	100		62	38

findings that activation of this pathway is common in melanoma, although a strong relation to existing prognostic factors was not seen.

MATERIALS AND METHODS

Patient material

The tissue blocks of specimens from 100 patients were retrieved from the archival files of the department of anatomical pathology at Royal Prince Alfred Hospital, Sydney, Australia. These had been surgically excised during the period 2000–3. The cases consisted of (1) 42 primary cutaneous melanomas, including 18 nodular melanomas, 14 superficial spreading melanomas, four desmoplastic melanomas, three in situ melanomas, two acral lentiginous melanomas, and one lentigo maligna (Hutchinson's melanotic freckle) melanoma; (2) 21 subcutaneous melanoma metastases including two in fibrofatty tissue and one in skeletal muscle; (3) 17 lymph node metastases; (4) 10 dysplastic naevi; and (5) 10 compound naevi. Dysplastic naevi were diagnosed on the basis of histological criteria: (1) somewhat symmetrical, (2) uniform slight elongation of rete in the lentiginous compartment with bridging nests or anastomosing rete, (3) eosinophilic fibroplasia or lamellar fibroplasia present, (4) moderate cytological atypia, and (5) absence of mitoses in the dermis.^{21, 22} The 42 primary cutaneous melanomas were from patients treated at the Sydney Melanoma Unit over the period December 2000 to March 2002. Haematoxylin and eosin stained sections of all 100 cases were reviewed by five of the authors (SWM, RAS, AAP, CSL, and LQZ). Depending on the Breslow thickness, primary melanomas were separated into thin (≤ 1 mm) and thick (> 1 mm) melanomas and also according to radial and vertical growth phase, mitosis, Clark level, and cytological features. Samples of normal skin from adjacent tumours were included. All patients with melanoma had regular follow up at the Sydney Melanoma Unit. Median follow up was 43.5 months (range, 21–50).

Immunohistochemistry

Sections (5 μ m thick) were cut from formalin fixed, paraffin wax embedded tissue blocks. Sections were dewaxed in xylene and rehydrated through graded concentrations of alcohol. After three periods of microwave antigen retrieval in 0.01 mol/litre citrate buffer (pH 6.0) for five minutes each,²³ they were incubated at room temperature for one hour with rabbit antihuman ERK1/2 antibody (polyclonal IgG; Santa Cruz, San Diego, California, USA) at a 1/1000 dilution in Tris buffer. For phosphorylated (activated) ERK (p-ERK) staining, antigen retrieval was carried out in a 100°C water bath for one hour after adding EDTA buffer, pH 8.6.²³ The sections were then incubated with mouse antihuman p-ERK antibody (monoclonal IgG; Santa Cruz) at room temperature for one hour at a 1/100 dilution in Tris buffer. Binding of the primary antibodies was visualised using the Vectastain ABC kit

(Vector Laboratories, Burlingame, California, USA) and DAB kit (Dako, Carpinteria, California, USA). The sections were then stained with haematoxylin. Negative controls of mouse IgG/Tris buffer were included in each experiment. Staining of prostate and breast carcinoma were used as a positive control for ERK1/2 and p-ERK, respectively.^{24, 25}

The immunohistochemical score (IRS) for each case was determined by combining an estimate of the percentage of immunoreactive cells (quantity score) with an estimate of the staining intensity (intensity score). It was calculated by multiplying the percentage of positive cells divided by 10 by the intensity score. Staining intensity was scored on an arbitrary scale of 0–3, where 0 was no staining, 1 was weak, 2 was moderate, and 3 was strong. The pattern of distribution (focal or diffuse) was also assessed for each case.

Statistical analysis

Statistical analysis was performed with Microsoft Excel 2000 software and "JMP Statistics Made VisualTM" software (SAS Institute Inc, Trunbull, Connecticut, USA). The correlation between ERK1/2 and p-ERK staining and groups of naevi and melanoma was performed using the one way ANOVA two tailed *t* test. Comparisons for each pair were made using the Student's *t* test and comparisons for all pairs using the Tukey-Kramer HSD method. The comparisons for p-ERK expression in nodular melanoma, desmoplastic melanoma, superficial spreading melanoma, dysplastic naevi, and compound naevi used the one way ANOVA two tailed *t* test, the Student's *t* test for each pair, and the Tukey-Kramer HSD multiple comparison tests; acral lentiginous melanoma, in situ melanoma, and lentigo maligna melanoma were excluded from this comparison because of the small numbers of these cases studied. The correlation between p-ERK expression in each primary melanoma and tumour Breslow thickness and mitotic rate was assessed using regression analysis.

Disease free survival (DFS) and overall survival (OS) were calculated using Kaplan–Meier estimates. Differences in DFS and OS between patients with melanoma according to tumour thickness (≤ 1 mm thickness and > 1 mm thickness) and p-ERK expression (above and below the median % value or above and below the IRS score) were compared using log rank and χ^2 statistical methods.²⁶ Other arbitrary cut off values for percentage of p-ERK positive cells and IRS score were also examined.

RESULTS

Table 1 shows the types of tumours and their corresponding patient demographics. The patients' ages ranged from 16 to 93 years and the median age was 66 years. Thirty eight (38%) were female and sixty two (62%) were male. For the 42 cases of primary melanoma, ages ranged from 23 to 84 years and the median age was 69 years. Fourteen were female and twenty eight were male. The Breslow thickness of the tumours ranged from 0.1 to 16 mm. There were 24 cases of primary melanoma > 1 mm and 18 cases of primary melanoma ≤ 1 mm or 28 vertical growth phase and 14 radial growth phase cases.

As shown in fig 1, ERK1/2 was expressed to varying degrees in all cases. The percentages of positive cells ranged from 40% to 100%. The mean percentages of positive cells in dysplastic naevi, thin melanomas, and thick melanomas were 99.6%, 98.9%, and 84.1%, respectively (table 2). ERK1/2 appeared to be expressed in both the cytoplasm and nucleus of melanocytic cells. The distribution of staining was diffuse rather than focal and ranged in intensity from 1 to 3 (fig 1A–F). Only low amounts of ERK1/2 were detected in melanocytes of normal skin (fig 1G). In seven of 24 cases of thick

Figure 1 Extracellular signal regulated kinase 1/2 expression in different types of primary and secondary melanocytic tumours. (A) Compound naevus; positive cells, 80%; immunoreactive score (IRS), 16; original magnification, $\times 100$. (B) Dysplastic naevus; positive cells, 100%; IRS, 20; original magnification, $\times 200$. (C) Melanoma ≤ 1.0 mm; positive cells, 100%; IRS, 30; original magnification, $\times 200$. (D) Melanoma > 1.0 mm; positive cells, 98%; IRS, 19.6; original magnification, $\times 100$. (E) Desmoplastic melanoma; positive cells, 90%; IRS, 18; original magnification, $\times 200$. (F) Metastatic melanoma: (1) subcutaneous metastasis; positive cells, 100%; IRS, 30; original magnification, $\times 100$; (2) lymph node metastasis; positive cells, 85%; IRS, 12.8; original magnification, $\times 100$. (G) Normal skin melanocytes; positive cells, $< 2\%$; IRS, < 2 (arrow); original magnification, $\times 400$.

melanoma, ERK1/2 expression was more intense at the deep margin of the tumour.

p-ERK was expressed in 95 melanomas and naevi, with the percentage of positively staining cells ranging from 5% to 100%. The mean percentages of cells positive for p-ERK in compound naevi, dysplastic naevi, thin melanomas, thick melanomas, and subcutaneous melanoma metastases were 32.4%, 54.5%, 64.6%, 77.1%, and 76.3%, respectively. These differences were highly significant using the one way ANOVA two tailed *t* test ($p < 0.0005$; table 2). The mean percentage of cells in thick melanomas with activated p-ERK was higher than in dysplastic naevi ($p < 0.01$), compound naevi ($p < 0.0001$), and lymph node metastases ($p < 0.005$) using the Student's *t* test, and was higher than in compound naevi ($p < 0.0001$) and lymph node metastases ($p < 0.005$) (fig 2) using the Tukey-Kramer method for multiple comparisons. In patients with metastatic melanoma, p-ERK was expressed in a higher percentage of cells in subcutaneous metastases compared with lymph node metastases ($p < 0.005$) and

compound naevi ($p < 0.001$) (fig 2). The distribution of positive cells was heterogeneous. The staining intensity was weaker in benign lesions than in malignant lesions. Most naevi had a staining intensity of 1 (fig 3A–F). p-ERK was not detected in melanocytes of normal skin (fig 3G). p-ERK expression in thick melanomas was more intense towards the tumour margins, particularly the deep margin.

The IRS was estimated in the radial and vertical growth phases of primary melanoma (table 3). The correlation between p-ERK expression and histological subtypes of melanoma was also assessed. There was a higher percentage of cells positive for p-ERK in nodular melanomas than in compound naevi ($p < 0.0005$), and a trend towards a higher percentage in nodular melanomas compared with superficial spreading melanomas ($p = 0.27$) (fig 4). The relation of p-ERK to thickness or the dermal mitotic rate in the primary melanoma was also assessed. As shown in fig 5 there was a weak but not significant trend for p-ERK to be higher in thick melanoma ($p = 0.17$) and there was also a trend towards

Table 2 ERK1/2 and p-ERK in the different types of melanocytic lesions

increased p-ERK expression with increased dermal mitotic rate, although this was not significant ($p = 0.47$).

DFS and OS

During follow up of the 42 patients with primary cutaneous melanoma (median follow up 43.5 months), 15 patients developed recurrent melanoma. Among those, five had locoregional recurrences, two had distant metastases, and eight patients had both. Nine patients died with melanoma. No patients with melanoma ≤ 1 mm thickness had a recurrence or died (fig 6A). In patients with melanoma > 1 mm thickness there were trends for differences in DFS ($\chi^2 = 0.27$, $p = 0.6$) and OS ($\chi^2 = 1.47$, $p = 0.23$) in

Figure 4 Mean percentage of cells positive for extracellular signal regulated kinase 1/2 (ERK1/2) and p-activated ERK1/2 (p-ERK) in naevi and different histopathological types of primary melanoma. patients with percentages of p-ERK positive cells above and below the median % value (80%) (fig 6B). There was no relation between IRS score and DFS or OS except when comparisons were made between survival in those with IRS scores ≤ 20 (20 patients) or > 20 (three patients) (DFS: $\chi^2 = 6.98$, $p = 0.008$; OS: $\chi^2 = 9.95$, $p = 0.002$). There was no significant difference between OS in patients with IRS scores above or below the median IRS of 15 ($p = 0.8$). There were also no differences in DFS or OS at different cutoff values for percentage of p-ERK positive cells (> 50%/≤ 50%, > 60%/≤ 60%, and > 70%/≤ 70%; data not shown).

Figure 3 Activated extracellular signal regulated kinase (p-ERK) expression in different types of primary and secondary melanocytic tumours. (A) Compound naevus: (1) p-ERK(+); positive cells, 95%; immunoreactive score (IRS), 9.5; original magnification, ×100; (2) p-ERK(-); original magnification, ×200. (B) Dysplastic naevus; positive cells, 50%; IRS, 5; original magnification, ×200. (C) Melanoma ≤ 1.0 mm; positive cells, 97%; IRS, 19.4; original magnification, ×200. (D) Melanoma > 1.0 mm; positive cells, 98%; IRS, 24.5; original magnification, ×100. (E) Desmoplastic melanoma; positive cells, 70%; IRS, 7; original magnification, ×200. (F) Metastatic melanoma: (1) subcutaneous metastasis; positive cells, 98%; IRS, 19.6; original magnification, ×200; (2) lymph node metastasis, p-ERK(+); positive cells, 90%; IRS, 18; original magnification, ×200; (3) lymph node metastasis, p-ERK(-); original magnification, ×200. (G) Normal skin melanocytes; p-ERK(-); original magnification, ×400.

Figure 5 Percentage of activated extracellular signal regulated kinase (p-ERK) positive tumour cells in primary melanoma correlated with tumour thickness. There was a trend towards increased p-ERK expression with increased tumour thickness, although this was not significant ($R^2 = 0.0454$, $p = 0.17$).

DISCUSSION

In previous studies we found that activation of the ERK1/2 pathway inhibited apoptosis in a wide range of melanoma lines. Activation of this pathway is also known to be involved in regulation of the cell cycle through the retinoblastoma protein pathway.¹⁹ In view of these findings, we and others have hypothesised that activation of this pathway may be important in the development and progression of melanoma.^{14–20} Our present study sought to obtain more evidence for this hypothesis by studies on sections of formalin fixed tissue that could not be influenced by in vitro manipulation and tissue culture.

The results showed that activated ERK1/2 (p-ERK) was found more frequently in primary melanoma than in naevi and that within naevi, p-ERK expression was higher in dysplastic naevi than in compound naevi. Within melanoma, nodular melanoma had higher expression than superficial spreading forms of melanoma. Therefore, increased expression of p-ERK correlated in general with the malignant

potential of the lesions, ranging from compound naevi having low potential followed by dysplastic naevi, superficial spreading melanoma, and nodular melanoma. Further support for a relation with progression of melanoma was the finding that p-ERK was increased at the deeper margins of primary melanoma where the tumour was expanding and invading into the dermis.

“Increased expression of p-ERK correlated in general with the malignant potential of the lesions, ranging from compound naevi having low potential followed by dysplastic naevi, superficial spreading melanoma, and nodular melanoma”

We examined whether p-ERK expression was related to other known prognostic features such as depth and mitotic rate of the primary tumour. There was a non-significant trend for the depth of melanoma to be associated with p-ERK expression, but there was no clear association with the mitotic rate. These results may indicate that other signalling pathways, such as the protein kinase B (Akt) pathway,¹⁹ are also involved, and that these impact on the mitotic rate, which was used as a measure of cell division in our study. The higher percentage of cells positive for p-ERK in nodular melanoma compared with benign naevi and superficial spreading melanoma is of interest because activating mutations of *N-ras* (upstream of ERK1/2) have been reported to be more frequent in nodular melanoma and lentigo maligna melanomas.^{27–28} Unfortunately, we were not able to assess *N-ras* mutations in our samples. The expression of p-ERK in subcutaneous metastases was similar to that seen in thick melanoma, but an unexpected finding was the significantly lower percentage of tumour cells positive for p-ERK in 17 lymph node metastases (48.5%) compared with metastases in subcutaneous sites (76.3%) (Student’s *t* test, $p < 0.005$). An explanation for these findings is not readily apparent. Mutations of *N-ras* and *B-RAF* were reported to be more frequent in cutaneous or soft tissue melanoma metastases,²⁹ and this may in part account for the differences. Alternatively, it is possible that the microenvironment in lymph nodes inhibited activation of the ERK1/2 pathway. Further study of metastases at these sites is required to answer this question.

In addition to examining the correlation between p-ERK expression in melanoma and clinicopathological features, we

IRS, immunoreactive score; p-ERK, activated extracellular signal regulated kinase; RGP, radial growth phase; VGP, vertical growth phase; %, mean percentage.

Figure 6 Kaplan-Meier estimates of overall survival (OS) after excision of primary cutaneous melanoma. (A) OS of patients with melanoma ≤ 1 mm thickness versus > 1 mm thickness. (B) OS of patients with thick melanoma having % activated extracellular signal regulated kinase (p-ERK) below the median value ($\leq 80\%$) versus patients with values above the median ($> 80\%$).

tested its association with DFS and OS in patients with primary melanoma. There were no recurrences or deaths in patients with thin melanoma (≤ 1 mm), but in patients with melanoma > 1 mm thickness, those with p-ERK % values above the median tended to have a lower OS than those with values below the median ($p = 0.23$). These findings provide further support for the view that activation of ERK1/2 is related to the progression of melanoma. However, the patient numbers in our study were small and did not warrant multivariate analysis of the data.

The mechanisms underlying activation of the ERK1/2 kinases are not clear. ERK1/2 kinases may be activated by ligand interaction with tyrosine kinase receptors via RAS kinase, RAF kinase, and MAPK kinase or by crosstalk with the protein kinase C pathway.^{20–30} Therefore, it is possible that paracrine or autocrine growth factors, such as fibroblast growth factor³¹ or chemokines,²⁹ are responsible for activation of the pathway. Activating mutations of B-RAF upstream of ERK1/2 are relatively common in melanoma and naevi.^{32–35} If this was the only factor involved, p-ERK would be expected to be expressed equally in naevi and melanomas, which was not the case in our study or in other studies. It has been found that transfection of mutated B-RAF into melanocytes results in activation of ERK1/2³⁰ but B-RAF is not required for signalling by mutated N-ras. N-ras mutations are believed to be infrequent in melanoma (occurring in approximately 11%).³⁶ In addition, studies by others have shown that divergent pathways may exist upstream of ERK1/2.³⁷ Interestingly, high amounts of p-ERK are seen in Spitz naevi, but these lesions usually have a low mitotic rate, possibly because of high concentrations of p16 cell cycle inhibitory proteins.³⁸

Irrespective of the cause of ERK activation in melanoma, our data support the concept that inhibition of this cell signalling pathway might be useful in the treatment of melanoma.^{39–42} Our previous studies showing the importance of ERK1/2 in the resistance of melanoma to apoptosis¹⁴ also indicate that this pathway may be an important target in the treatment of melanoma with apoptosis inducing agents. This has been supported by the promising results of studies in preclinical models with the MAPK kinase inhibitor CI1040,⁴³ and phase I/II studies in patients treated with Carboplatin and Paclitaxel together with the Bayer BRAF inhibitor, BAY 43-9006.⁴⁴ Our present study suggests that approximately 90% of patients with metastatic disease have some degree of activation of this pathway and hence may benefit from this treatment approach.

ACKNOWLEDGEMENTS

We thank the staff of the Department of Anatomical Pathology, Royal Prince Alfred Hospital, especially S Davies and D Maguire, for their assistance with immunohistochemistry; the staff of the Oncology and Immunology Unit of the Newcastle Mater Misericordiae Hospital for their assistance and comments; and M Colman from the Sydney Melanoma Unit Database for follow up information.
