A TECHNIQUE FOR ESTIMATING THE BONE MARROW CELLULARITY IN VIVO USING $^{59}$Fe*

BY

H. D. SUIT

From the Department of Radiotherapy, Oxford

(RECEIVED FOR PUBLICATION NOVEMBER 1, 1956)

This is a preliminary note on an attempt to develop a technique for estimating the bone marrow cellularity in man. At present there is no means of making such an estimate, and discussions of the probably mitotic interval and bone marrow life span of the different stages of erythrocyte precursors are based on calculations of the known average red cell life, the total numbers of red cells and reticulocytes in the peripheral blood, and the relative numbers and mitotic indices of the different erythrocyte precursors.

Principle of the Method

The method is based on the assumption that essentially all of the $^{59}$Fe which appears in the peripheral erythrocytes after injection of the isotope has come from the bone marrow, except for that taken up directly by the reticulocytes in the peripheral blood.

Radioactive iron ($^{59}$Fe), after an intravenous injection, is rapidly cleared from the plasma (half clearance time is 90-120 minutes), mainly by the bone marrow (Huff, Hennessy, Austin, Garcia, Roberts, and Lawrence, 1950). By 12 or 24 hours after the injection only a small percentage of the injected $^{59}$Fe is in the peripheral erythrocytes, and there is essentially none in the plasma; the radioactivity found in a bone marrow sample collected at that time is due largely to the $^{59}$Fe in the erythrocyte precursors of the marrow sample. From a nucleated cell count, a differential count, and radioactivity assay of the marrow sample, the ratio of erythrocyte precursors to radioactivity can be established. The appearance of the $^{59}$Fe in the peripheral blood is followed in daily blood samples; after eight days there is usually no significant further increase. The proportion of the injected dose appearing in the peripheral blood by the eighth day is taken to be the same as that taken up directly by the marrow after the injection. On this basis, the portion of the dose in the marrow at 24 hours would be that which went into the marrow at 0 hours, minus that which had already appeared in the blood. From this the total marrow cellularity can be estimated from the ratio, radioactivity of marrow sample/cellularity of marrow sample = radioactivity of the total marrow/cellularity of the total marrow.

Some attention has been given to the assumptions made in the use of this method. First, that of the order of 80% of the $^{59}$Fe that is cleared from the plasma is taken up directly into the erythrocyte precursors and that it will appear in the blood over the following eight days. Huff et al. (1950) found that the increase in the radioactivity of human bone marrow (sacral) in vivo after a $^{59}$Fe injection was the inverse of the fall of activity of the plasma. Similar observations have been made on rabbit bone marrow where the bone was excised and the radioactivity of the marrow determined directly (Huff et al., 1950). Autoradiographs prepared on rabbit bone marrow and peripheral blood after an injection of $^{59}$Fe indicated that as the number of peripheral erythrocytes containing radioactive iron increased there was a fall in the isotope content of the bone marrow normoblasts (Suit, Lajtha, Oliver, and Ellis, 1957). The second assumption is that the bone marrow sample studied is a true representative of the marrow throughout the body. Rekers and Coulter (1948) in a detailed study found that bone marrow samples collected from ribs, femora, humeri, and tibae of adult dogs all had the same distribution of nucleated cells, although the cellularity of the specimens varied greatly. Presumably morphologically similar cell populations have the same functional activity. The third assumption is that the radioactivity of the reticulocytes in the bone marrow samples is the same as that in the peripheral blood. That is, that the reticulocytes of the marrow preparation (collected as 5-8 ml. volume) are of the same relative number and age distribution as those

* This work is part of a project supported by a full grant from the British Empire Cancer Campaign.
of the peripheral blood. Comparisons of the number

of reticulocytes in bone marrow particles and

peripheral blood have given a ratio of about 2:4:1

(Ungricht, 1938; Seip, 1953). In three cases of the

study for this report, reticulocyte counts were made

on the bone marrow preparation and on the

peripheral blood; the results were 0.6 and 0.7:

0.7 and 0.6; and 1.4 and 1.2% for the marrow and

blood respectively (based on counts of 1,000 cells

in each instance). These data do not demonstrate a

difference. However, even if the reticulocyte level

of the marrow were four times that of the peripheral

blood, if the marrow was diluted by only a factor

of 10, the ratio of the marrow preparation : per-

ipheral blood reticulocyte level would be 1.3 : 1.

Seip (1953) in 13 cases compared the number of

erythrocytes with the number of nucleated marrow

cells in bone marrow particles and found a range of

12 to 43 : 1. The same comparison in the six cases

presented here gave a range of 106 to 443 : 1. The

reason for this difference is that in the method

described here the marrow sample is greatly diluted

with peripheral blood, which has the advantage of

more accurate volume determination as well as
dilution of marrow reticulocytes. These data would

suggest that the bone marrow preparations as used

in these total cellularity estimations contained at

most 40 to 50% more reticulocytes than the

peripheral blood. An increase of 50% in the radio-

activity of the non-nucleated red cells of the marrow

preparation would probably be more than correct

for the greater number of reticulocytes in the marrow

preparation, even though some of those were young

reticulocytes with a high iron uptake. Autora-

diography studies in rabbits showed 20% higher

average grain counts over marrow reticulocytes

than over blood reticulocytes. However, even if

radioactivity in the erythrocytes in the marrow

preparation were corrected by this factor of 50%,

it would not increase the final value for the cell-

ularity by more than 20% (no such corrections are

made on any of the following data presented).

A final assumption is that there is no death of the

erthrocyte precursors of the bone marrow; that is,

all of the nucleated erythrocyte precursors that take

up the 59Fe do mature and are released into the

peripheral blood. Giblett, Coleman, Pirzio-Birol, Donohue, Motulsky, and Finch (1956) have pre-
sented evidence to suggest that in certain varieties

of anaemia some of the normoblasts do not mature

into erythrocytes, and have referred to this as

“ineffective erythropoiesis.” Whether or not this

process occurs to a measurable extent in the normal

marrow is unknown. If it is a quantitatively small

process normally, then its effect on the results of

the cellularity estimation would be to underestimate the

value, probably not more than 10% (as 80% or more

of the injected 59Fe is considered to be in the normo-

blasts at the time of measuring the activity of the

marrow sample).

Sample Calculation (Experiment 1011)

59Fe was injected on May 24, 1955 (this is equivalent
to a total count rate of 3.79 × 10^5 cpm.). Bone marrow

was collected on May 25.

1. Radioactivity of 10 ml. bone marrow preparation
due to erythrocyte precursors:

(a) Total radioactivity of the sample = 47 cpm.

(b) Red cell count of the sample = 2.72 × 10^10

R.B.C. 10 ml.

(c) Activity of 10 ml. peripheral blood = 25 cpm.

R.B.C. in 10 ml. peripheral blood = 5.4 × 10^10 R.B.C.

:: 2.72 × 10^10 R.B.C. would have 12 cpm.

(d) Activity of the marrow preparation due to

59Fe in the erythrocyte precursors: 47 − 12 = 35 cpm.

2. Bone marrow sample cellularity

10,600 nucleated cells per mm.9-10

1.06 × 10^5 nucleated cells in 10 ml.

3. Total radioactivity of the bone marrow.

(a) Percentage of the injected dose that went
directly into the erythrocyte precursors = 100%.

(b) Activity in erythrocyte precursors on May 25 =
total 59Fe injected − 59Fe in peripheral blood on

May 25.

= total counts injected − (cpm. ml. whole blood

− blood volume)

= 3.79 × 10^4 − 2.5 × 4,700

= 3.79 × 10^4 − 0.11 × 10^5

= 3.68 × 10^5 cpm.

4. Total number of bone marrow nucleated cells

marrow sample cellularity × whole bone marrow activity

activity of marrow sample

= 1.06 × 10^5 × 3.68 × 10^5

= 3.5 × 10^11

= 1.11 × 10^12 nucleated cells.

5. Bone marrow differential count

14% of the total nucleated cells are erythrocyte

precursors.

:: total number of erythrocyte precursors

= 15.4 × 10^10.

Discussion

Results from such studies of six patients are
presented in Table I. There is a wide range (6 to 24
× 10^9) in the estimated total number of erythrocyte

precursors. The range for five cases was 10 to

24 × 10^9 cells. These data when compared with

the probable daily erythrocyte production indicate a
short life span in the bone marrow for the normoblasts, i.e., less than one day.

The most likely source of error is the allowance for the radioactivity in the erythrocytes (reticulocytes) of the marrow preparation. As the reticulocytes of the marrow are younger and have a higher iron uptake than those of the peripheral blood the calculated result is an under-estimate of the total cellularity.

* Product of blood volume and erythrocyte count. Blood volume was estimated from the \(^{55}\)Fe determined plasma volume on a venous haematocrit.
† On the basis of an average life span of 120 days.

Also the patients used for these studies, although in good general condition, nevertheless had malignant diseases which often result in a progressive anaemia. The figures presented in Table I are not, therefore, considered to represent normal values but probably values below normal. Osgood (1954) calculated the number of erythrocyte precursors in normal human marrow to be of the order of 40 to 60 \( \times 10^{10} \) cells.

This technique appears to offer an opportunity of estimating the marrow cellularity, but further experiments are needed to determine the radioactivity of the reticulocytes in the dilute bone marrow samples.
