Exudative lesions in diabetes mellitus

G. I. HORSFIELD and R. LANNIGAN

From the Department of Pathology, University of Birmingham

SYNOPSIS

Exudative lesions and capsular drops have been examined in a renal biopsy series of 25 diabetics and a post-mortem series of 100 consecutive diabetics. Electron microscopy of a capsular drop and an exudative lesion is described. Exudative lesions were found in 48% of the biopsies and 47% of the necropsy material. Capsular drops were found in 60% of the biopsies and 29% of the necropsy material. No correlation with age, proteinuria, hypertension, or uraemia was noted. The incidence of both types of lesion increased with the known duration of the diabetes.

In addition to the nodular lesion (Kimmelstiel and Wilson, 1936) and the diffuse lesion (Fahr, 1942; Laipply, Etizen, and Dutra, 1944) the renal glomeruli of diabetics may contain deposits of eosinophilic, hyaline, or granular material having some of the staining reactions of fibrin. These deposits are not specific for diabetes since similar lesions may be found in a variety of renal conditions. Most of the previous descriptions have been from post-mortem material and it has been generally considered that the deposits were terminal. Similar lesions have been found in renal biopsy specimens from diabetics of all ages and severity and the incidence is much higher than might be expected. This communication deals with a series of renal biopsies from 25 diabetics and a series of post-mortem specimens from 100 consecutive cases of diabetes mellitus.

The term 'exudative lesion' was used by Hall (1952) and, although suggesting a pathogenesis which is not yet proven, is in common use. Other authors have incorporated the term 'fibrinoid' in their descriptive titles, e.g., 'fibrinoid crescents' (Spühler and Zollinger, 1943), 'hyaline-fibrinoid lesion' (Koss, 1952), whilst Muirhead, Montgomery, and Booth (1956) described the lesion as the 'acellular hyaline lesion'. Barrie, Askanaoy, and Smith (1952) distinguished two types, one affecting the glomerular loops which they called the 'fibrin cap', and one affecting the parietal layer of Bowman's capsule which they called the 'capsular drop'. We have used the term 'exudative lesion' to describe eosinophilic deposits within the glomerular tuft and 'capsular drop' for the lesion associated with Bowman's capsule.

MATERIALS AND METHODS

BIOPSY SERIES

Twenty-five patients were selected aged between 12 and 54 years and of varying duration of diabetes since diagnosis. The earliest biopsy was carried out three weeks after the onset of acute diabetes and the latest 28 years after diagnosis. The patients had varying severity of diabetes, many had proteinuria, and a few were mildly hypertensive; none were uraemic.

The renal biopsy material, obtained by the method of Muehrcke, Kark, and Pirani (1955), was fixed in formol-corrosive and serial sections taken almost completely through the specimens. These were stained routinely with haematoxylin and eosin, periodic acid Schiff, and Van Gieson's fluid. Several of the biopsies were split and one part was fixed in 1% buffered osmium tetroxide for 30 to 60 minutes and embedded in methacrylate for electron microscopy. In one of these specimens a capsular drop and an exudative lesion within a hyalinized glomerulus were located and examined on a Siemens series 6 electron microscope.

POST-MORTEM SERIES

The post-mortem series consists of specimens from 100 consecutive patients dying from various causes who had suffered from diabetes mellitus. Sections were taken from both kidneys, fixed in 10% formal saline, and stained routinely with haematoxylin and eosin. Samples were stained with the periodic-acid-Schiff reaction, Van Gieson's fluid, Mallory's phosphotungstic acid haematoxylin, Lendrum's acid picromallory, picromallory V, and Martius Scarlet Blue (Lendrum, Fraser, Slidders, and Henderson, 1962). Control sections of glomeruli containing thrombi were similarly stained. In some post-mortem material fat was demonstrated by the Sudan IV method.

Lesions were recorded as present or absent in any particular case.

RESULTS

With routine haematoxylin and eosin stains after...
formalin or formal-corrosive sublimate fixation exudative lesions appear as highly eosinophilic masses of varying shape, usually crescentic, round or oval, predominantly situated at the periphery of the glomerular loops (Fig. 1). Frequently they contain globules of fat and in some examples these may form the major part of the lesion (Fig. 2). They may be single or multiple and vary in size. Nuclear material is not present. In most cases the deposit appears to be inside dilated capillary loops and is intimately related to the endothelial side of the capillary basement membrane. In other cases, however, and especially in severely damaged glomeruli, the site of the material is difficult to determine in relation to capillaries (Fig. 3). In a few cases very similar lesions appear to fill the capillary lumen. These can frequently be distinguished from fresh thrombi by their shape and sometimes by their staining reactions.

The capsular drop is an eosinophilic or sometimes slightly basophilic hyaline mass containing variable amounts of fat but no nuclear material. It is usually smaller and less eosinophilic than the exudative lesion and appears to be attached to the inner surface of Bowman’s capsule (Fig. 4), often close to the hilum of the glomerulus. Serial sections readily show that the lesion is not continuous with the ‘fibrinoid’ or ‘hyaline’ material frequently found in the afferent and efferent arterioles of the glomerulus in diabetes. In a few cases the epithelial cells of Bowman’s capsule contain large amounts of lipid but no fibrin staining material (Fig. 5). These are usually bigger than the capsular drops and it is doubtful if they represent the same type of lesion although differentiation may be difficult in small lesions.

STAINING REACTIONS The staining reactions were very variable. All were positive with periodic-acid-Schiff stain, but, to varying degrees, stained yellow with Van Gieson’s fluid, were sometimes orange with Mallory’s phosphotungstic acid haematoxylin but usually stained blue, and were usually red with the acid picro-Mallory, picro-Mallory V, and

Martius Scarlet Blue. Although the post-mortem material was formalin fixed the control sections containing thrombi regularly stained as for fibrin.

**Electron Microscopy**

One capsular drop was located in a glomerulus showing a diffuse lesion and in another glomerulus from the same specimen an exudative lesion was noted. The latter glomerulus was almost completely hyalinized.

**Capsular Drop**

The drop consists of dense osmiophilic material situated on the inner surface of Bowman's capsule and separated from Bowman's space by a narrow homogeneous non-osmiophilic layer (Fig. 6). At this area the epithelial cells of the glomerulus are closely applied to the capsular drop and it is difficult to distinguish the cells of Bowman's capsule. At the periphery, however, the lesion is clearly beneath the cells of Bowman's capsule, and layers of osmiophilic material similar to that in the main capsular drop are found within the capsule itself. The osmiophilic material is amorphous and no cytoplasmic components have been recognized.

**Exudative Lesion**

In the exudative lesion within the glomerulus there is a dense osmiophilic deposit which appears to involve all structures except the basement membrane. The glomerulus itself is...

severely damaged and there are few open loops. In
many areas the architecture is destroyed and loops
are replaced by masses of material resembling base-
ment membrane. It is impossible in these areas to
determine where the lumen of the capillaries has
been originally. In the area of the exudative lesion
there is an intimate mixture of dense osmiophilic
material and the abnormal basement-membrane-
like material. In one open capillary loop the osmi-
ophilic material is found lining the inner layer of
basement membrane in the situation normally
occupied by endothelial cytoplasm and in other
areas projects into the lumen. On the epithelial side
of the basement membrane is a similar deposit
occupying the area of the foot process layer and
extending into Bowman’s space. Within the capillary
loop there are strands and masses of basement-
membrane-like material surrounded by similar
osmiophilic material which projects into the lumen
(Fig. 7). No recognizable cytoplasmic components
were noted in this region of the osmiophilic material
but cytoplasm and nuclei were readily recognized
elsewhere. The impression gained from the pattern
was that the cytoplasm of endothelial and epithelial
cells was involved in the process.

INCIDENCE OF EXUDATIVE LESIONS AND CAPSULAR
DROPS The incidence of the histological type of
glomerular damage, exudative lesions, and capsular
drops is shown in Table I for the biopsy series and
Table II for the post-mortem series.

In the post-mortem series it is evident that
exudative lesions and capsular drops occur more
frequently when nodular lesions are present. In
the biopsy specimens only a few glomeruli are
available and the incidence of cases with Kimmel-
stiel-Wilson lesions is probably underestimated. The
biopsy series is also a highly selected group and
direct comparison with the post-mortem series is
probably not justifiable.

CLINICO-PATHOLOGICAL CORRELATION

AGE AND DURATION OF DIABETES The relationship
between age, known duration of diabetes, and the
presence of exudative lesions and capsular drops
in the post-mortem series is shown in Tables III and
IV.

The majority of the patients were above the age
of 50 years and there does not appear to be any direct
connexion with age. There is, however, a distinct

trend for both exudative lesions and capsular drops to occur more frequently the longer the duration of diabetes. In the biopsy series the numbers in each group are too small to draw any firm conclusion but there is a similar trend.

In the biopsy series the youngest patient with exudative lesions and capsular drops was aged 12 and had been diabetic since infancy. In the post-mortem series the youngest patient with both lesions was 28 years old.

HYPERTENSION In the biopsy series 10 patients had a diastolic pressure slightly above 95 mm. of mercury but none were severely hypertensive. Of these 10 patients exudative lesions were found in six and capsular drops in six. Only two cases did not have either lesion. In the 15 normotensives, exudative lesions were found in four and capsular drops in seven. Five cases showed neither exudative lesions nor capsular drops. There is no significant difference between the incidence of either exudative lesions, capsular drops, or both between the hypertensive and normotensive cases.

In the post-mortem series there was also no statistically significant difference between normotensives and hypertensives.

URAEMIA In the biopsy series none of the patients was uraemic and in the post-mortem series no correlation was noted with uraemia.

PROTEINURIA No significant difference in the incidence of exudative lesions or capsular drops was noted in cases with or without proteinuria.

DISCUSSION

The eosinophilic material in exudative lesions gave staining reactions some of which were positive for fibrin. However, there is no specific chemical stain for fibrin. In the lesions contained within the glomerular tuft we have noted on electron microscopy that the ‘fibrinoid’ material can be deposited either inside or outside the capillaries. Farquhar, Hopper, and Moon (1959) described a layer of fibrinoid between the endothelium and the basement membrane in an exudative lesion in diabetes. While the common site of the exudative lesion appears to be in this situation, in the most severely damaged glomeruli it is impossible to determine the situation of the deposit. We gained the impression from electron microscopy that the exudative lesion in our case involved endothelial and epithelial cytoplasm and was present inside and outside the basement membrane. This may represent a more advanced type of lesion. In a previous electron microscopy study of a similar type of lesion in experimental renal disease the ‘fibrinoid’ was found in Bowman’s space and extended through the cytoplasm of epithelial cells (Lannigan, 1963).

In a recent study we have noted a similar deposition of eosinophilic material in focal glomerulo-nephritis, and, while some of this material appeared to be free in Bowman’s space, in other areas it occupied the position of the foot-process layer and similar material was found on the endothelial surface of the membrane.

Recently Lendrum (1963) has claimed that the exudative lesion is a transudate of fibrin as is also the Kimmelstiel-Wilson lesion. He describes the process as ‘plasmatic vasculosis’. It appears likely that the exudative lesions are produced by deposits or transudates containing various proteins and lipids but it is also possible that cellular necrosis can contribute to the appearance in some cases.

The capsular drop has also been explained on the basis of exudation of plasma into Bowman’s capsule. In the lesion we have examined by electron microscopy there was no evidence of cytoplasmic involvement. The material appears to lie under the cellular lining and also was found in layers within the capsule itself.

Exudative lesions occurred more frequently in damaged glomeruli and the occurrence of exudative lesions and capsular drops in glomeruli which appeared normal on light microscopy was an unexpected finding. It has, however, been shown by various authors that alteration to the basement membrane can be noted on electron microscopy even in very early diabetics where light microscopy has indicated a normal glomerulus (Sabour, McDonald, and Robson, 1962; Lannigan, Blainey, and Brewer, 1964).

No correlation was noted with hypertension, uraemia, and proteinuria. Age by itself had little effect. There was, however, a trend for the exudative lesions and capsular drops to increase with the duration of diabetes.

In most published series of renal biopsies in diabetes, exudative lesions and capsular drops are not listed separately. Taft, Finckh, and Joske (1954) found 25%, Gellman, Pirani, Soothill, Muehrcke, and Kark (1959) 29%, Daysog, Dobson, and Brennan (1961) 61%, and Hatch, Watt, Kramer, Parrish, and Howe (1961) 28%. In the series of Honey, Pryse-Davies, and Roberts (1962) capsular drops were found in 50%. In the present series the incidence is higher than in most but in few of the other series were serial biopsies examined.

Daysog et al. (1961) found exudative lesions in four of 11 cases of ‘prediabetes’ and seven of 12 cases of diabetics of less than one year’s duration.
After six years’ duration they were present in virtually every specimen.

In one case in our biopsy series exudative lesions were noted in one biopsy and a repeat biopsy two years later showed a similar picture. This would indicate that exudative lesions are probably occurring frequently in diabetic glomeruli throughout the course of the disease and may contribute to the glomerulosclerosis.

We wish to thank Dr. Blainey and Dr. Malins for the clinical information. Some financial assistance was received from the Endowment Fund of the United Birmingham Hospitals.
