Possibility of normokalaemic primary aldosteronism as reflected in the frequency of adrenal cortical adenomas

I. DÉVÉNYI

From the Department of Pathology, University Medical School, Debrecen, Hungary

SYNOPSIS Adrenal cortical adenomas with diameters greater than 3 mm. were found in 185 (3.61 %, of 5,120 consecutive necropsies. A progressively higher incidence with increasing age was noted) 82 % of the adenomas occurring in cases in the age range 51-80 years.

On the basis of age distribution of adenomas and their connexion with hypertension, there does not seem to be sufficient proof to suppose that the cortical adenomas frequently found at necropsy can be held responsible for causing normokalaemic primary aldosteronism to the extent assumed by Conn (1964).

Primary aldosteronism has recently been isolated as a surgically curable form of hypertension in work described by Conn (1964), Conn, Cohen, and Rovner (1964), and Conn, Rovner, and Cohen (1965). They say that in about 20 % of cases of essential hypertension there are aldosterone-producing adrenal cortical adenomas but their recognition is impeded by the fact that hypokalaemia, the presence of which is indispensable for the diagnosis, only develops at the later stages of the disease, quite often after a 10-year period of hypertension. Consequently the disease may be regarded in the early stage as essential hypertension. The recognition of these cases of normokalaemic primary aldosteronism would be very important as they represent curable forms of hypertension.

Conn (1964) Conn *et al.* (1964), and Conn, Cohen, Rovner, and Nesbit (1965) have recommended a method for separating cases of normokalaemic primary aldosteronism from those of essential hypertension. By this means they have succeeded,

at least in one case up to date, in verifying their hypothesis. In addition, retrospective analysis of their previously observed cases has revealed the frequently delayed manifestation of hypokalaemia.

Since 'non-functioning' adrenal cortical adenomas have been found very frequently at necropsies and since, according to Conn (1964), 20 % of cases of essential hypertension should be classified as normokalaemic primary aldosteronism, necropsy material from this hospital has been evaluated with this diagnosis in mind.

PRESENT ANALYSIS

Reports of 5,120 consecutive necropsies carried out between 1956 and 1965 were examined (2,351 on females, 2,769 on males). The age distribution of cases is shown in Table I.

All cortical nodules with diameters greater than 3 mm. were considered to be adenomas, except for the yellow foci of spotted lipid depletions. Adrenal cortical adenomas were noted in 185 of the 5,120

¹ Fifteen years' history of hypertension, hypokalaemic vacuolated nephropathia.² Bronchial carcinoma.

necropsy reports (85 females, 100 males). Sixty-two per cent of adenomas had diameters of 1 to 2 cm., 77.3% were unilateral and solitary, 2.7% were unilateral and multiple, 14.6% were bilateral and solitary, and 5.4% were bilateral and multiple (Table II).

Eighty-two per cent of the adenomas belonged to cases in the age range 51-80 years.

Table III shows the data of cases with adenomas classified according to age and to hypertension and fatal illness. The ascertainment of hypertension was based on clinical data, heart weight, condition of the kidneys, and other necropsy data.

COMMENT

Analysing our observations, the frequency and age distributions of adenomas correspond with the investigations of other authors carried out with similar criteria (Commons and Callaway, 1948).

It is not the purpose of this study to analyse the relation between hypertension and cortical adenoma, although, after looking through the records without any statistical evidence, it has been our impression that the frequency of adenoma seems to be influenced mostly by age. In the pertinent literature there are numerous opinions emphasizing the close connexion between cortical adenomas and essential hypertension (Rinehart, Williams, and Cappeller, 1941;

Dawson, 1956; Fassbender, 1956; Shamma, Goddard, and Sommers, 1958; Sherwin, 1964), although other authors have denied such a connexion (Commons and Callaway, 1948).

The criteria of differentiating between cortical adenoma and nodular hyperplasia have not yet been defined. The arbitrary classification applied by us is fundamentally unsuitable but we have applied it because, according to Conn, Knopf, and Nesbit (1964), who have analysed 145 cases of the Conn syndrome, the lower size limit of adenomas was similar. According to Conn *et al.*, 'It is worthy of emphasis that the great majority of these tumours are small and that failure to visualize them by the various technics now in vogue does not exclude their presence.' In the same material there were multiple aldosteronomas in 9% of cases. Recently Cohen (1966) assumed that hyperplastic cortical nodules may be precursors of adenomas, and they are similar from a functional and histochemical point of view.

Summarizing 145 cases of primary aldosteronism, Conn *et al.* (1964) established that 72% of the patients belonged to the age range 31-49 years at the time of operation, and consequently with illnesses existing for some time. The 20% of cases of essential hypertension considered by Conn (1964) as of 'latent' primary aldosteronism should be expected to be by far the greatest number in the same age

range. On the contrary, in our material, 82% of adenomas belonged to cases in the age range 51-80 years. Only 11.8% of the adenomas belonged to cases in the age range 31-50 years, characteristic of primary aldosteronism.

Of the 22 adenomas from cases in the 31-50 age range, only seven were found to involve simultaneous hypertension (Table III). Among these cases there was one of the genuine Conn syndrome, with hypokalaemic nephropathia, one of Cushing's disease, two cases of brain tumour with hypertension, and one of renal hypertension.

As may be seen, there are only two cases of cortical adenoma with coexistent essential hypertension, in which the diagnosis of normokalaemic primary aldosteronism is possible.

From our 755 necropsy cases in the age range 31-50 years (Table I) 7% were of hypertension. Among these, 2.6% were of essential hypertension cases (renal hypertension 3.1%, brain tumour with hypertension 0.8%, malignant tumour with hypertension 0.4%). At the same time, the two cases of cortical adenoma with coexistent essential hypertension represent 0.26% of the 755 cases. It follows that among the essential hypertension cases from the age range 31-50 years, according to our necropsy

material, the incidence of normokalaemic primary aldosteronism might not be more than 10% (2.6 : 0.26). This maximal value is only half of the number suggested by Conn (1964). It does not seem sufficient material to suppose that in the post-mortem room the finding of frequently occurring 'non-functioning', 'incidental' cortical adenomas are to be held responsible for causing normokalaemic primary aldosteronism to such a great extent as has been supposed by Conn (1964).
