SYNOPSIS  A total of 1,102 clinical isolates of Gram-negative bacilli was obtained from four hospitals during 1967 and these cultures were tested for sensitivity to ampicillin. Approximately 80% of the strains of *Escherichia coli* and 90% of the strains of *Proteus mirabilis*, the two organisms most frequently isolated, were sensitive to ampicillin. Klebsiella-Enterobacter species and *Pseudomonas aeruginosa* were generally insensitive. Comparison of these results with data obtained in an earlier study with Gram-negative organisms isolated in 1961 showed that there had been no significant increase in the incidence of resistance of Gram-negative bacilli to ampicillin during the period 1961-67.

The majority of ampicillin-resistant strains of *E. coli* isolated in 1967 transferred ampicillin resistance to a sensitive strain of *E. coli* K12. Only four ampicillin-resistant strains of *E. coli* isolated in 1961 were available for transferable resistance tests but all four strains transferred ampicillin resistance. Infective or transferable resistance was therefore a feature of ampicillin resistance of certain Gram-negative bacteria before ampicillin became generally available for clinical use.

The relatively recent demonstration of transferable antibiotic resistance among bacteria (Watanabe, 1963) has led to renewed interest in the incidence of antibiotic resistance among Gram-negative bacilli, particularly as these organisms appear to be responsible for an increasing proportion of serious infections within hospitals (Watt and Okubadejo, 1967; Barrett, Casey, and Finland, 1968).

Shortly after the introduction of ampicillin into clinical use in mid-1961 several hundred freshly isolated cultures of Gram-negative bacilli were obtained from three London hospitals, and these organisms were tested for sensitivity to ampicillin, chloramphenicol, and tetracycline (Sutherland and Rolinson, 1964). During 1967 approximately similar numbers of isolates were obtained from the same three London hospitals as in 1961 and these were tested for sensitivity to ampicillin. In addition, a fourth hospital situated just outside the London area supplied approximately 300 cultures which were tested for sensitivity to ampicillin.

The data presented here show the incidence of resistance to ampicillin among Gram-negative bacilli isolated in 1967, and this is compared with the incidence of resistance among organisms isolated in 1961.

Received for publication 13 February 1969.
Sensitivity of Gram-negative bacilli to ampicillin after six years

the recipient strain E. coli K12/711 NX, a lactose-negative variant resistant to nalidixic acid. The mixed cultures of donor and recipient bacteria were cultured in 9 ml of Penassay broth, and, after overnight incubation at 37°C, were plated on MacConkey agar containing 25 μg/ml ampicillin and 20 μg/ml nalidixic acid; control plates containing either 25 μg/ml ampicillin or 20 μg/ml nalidixic acid were also inoculated with the mating mixtures. Inoculation of the plates was carried out with a multipoint inoculating device delivering approximately 0.003 ml of culture. After overnight incubation at 37°C the plates were examined for lactose-negative colonies growing in the presence of 25 μg/ml ampicillin and 20 μg/ml nalidixic acid. Lactose-negative colonies were subcultured into Penassay broth and retested for resistance to ampicillin.

RESULTS

SENSITIVITY TO AMPICILLIN OF ORGANISMS ISOLATED IN 1967 In all, a total of 1,102 strains of Gram-negative bacilli was tested, 233 from hospital 1, 240 from hospital 2, 342 from hospital 3, and 287 from hospital 4. The predominant organisms were E. coli (45-1%), P. mirabilis (22-1%) and Klebsiella-Enterobacter species (18-3%). The remainder comprised Ps. aeruginosa (9-7%), Proteus species (2-3%), and miscellaneous organisms (2-5%) such as paracolon bacteria, Achromobacter species, and Alkaligenes species (Table I).

Of the total of 497 strains of E. coli, 80% (397 strains) were sensitive to 5 μg/ml ampicillin or less. There was some variation between the four hospitals, ranging from 90-3% sensitivity at hospital 2 to 66% sensitivity at hospital 1. At the latter hospital the majority of resistant organisms were received at this laboratory in a single batch of cultures, and it is possible that this group of resistant organisms was associated with cross-infection occurring at the time these cultures were isolated.

The second most common pathogen, P. mirabilis (22% of isolates), was also predominantly sensitive, 93% (217 strains) being inhibited by 5μg/ml ampicillin or less. In fact, 208 out of these 217 strains were sensitive to 2.5 μg/ml ampicillin and more than half of the strains isolated were sensitive to 1.25 μg/ml ampicillin.

In contrast, Klebsiella-Enterobacter species, representing 18% of the total bacteria, were very much more resistant to ampicillin (64% sensitive to 5 μg/ml, 11.9% sensitive to 12.5 μg/ml), and strains of Ps. aeruginosa were uniformly insensitive. Proteus species (other than P. mirabilis) tended to be resistant to ampicillin, and the majority of the paracolon bacteria tested were also insensitive.

A number of strains of enterococci (Streptococcus faecalis), one of the more common of the pathogens associated with urinary tract infections, were also tested for sensitivity to ampicillin, but these results are not included in the tables as isolates were sent by only two of the four hospitals. Out of 39 strains tested only one strain was resistant to 5 μg/ml ampicillin; the majority (37/39 strains, 95%) were inhibited by 2.5 μg/ml ampicillin or less.

COMPARISON OF AMPICILLIN SENSITIVITIES OF GRAM-NEGATIVE BACILLI ISOLATED IN 1961 AND 1967 The cumulative percentage inhibition by ampicillin of the three most common species, namely, E. coli, P. mirabilis, and Klebsiella-Enterobacter, isolated at the three London hospitals in 1961 and in 1967, is illustrated in Figure 1. Details of the incidence of ampicillin sensitivity in 1961 and 1967 are presented in Table II.

The proportion of strains of E. coli isolated in 1967 (42.5%) was very similar to that of 1961 (44.5%) and the same was true for P. mirabilis (25.8% in 1961 and 23.4% in 1967). In general, the proportions of strains of these genera sensitive to ampicillin were similar for both studies. For example, 80.9% of E. coli isolated in 1967 were inhibited by 5 μg/ml ampicillin or less; the corresponding figure

1Organisms isolated at the same three London hospitals

for *E. coli* isolated in 1961 was 78-8% (Table II). It is true that 11% of the strains of *E. coli* isolated in 1967 were not inhibited by 250 μg/ml ampicillin, compared with a figure of 3% for 1961, but in part this may be due to cross-infection at one of the hospitals in 1967 as described previously. With *P. mirabilis* the proportion of ampicillin-sensitive strains isolated in 1967 (93-2%) was similar to that of 1961 (83-3%). If anything, this genus was more sensitive in 1967 than in 1961.

Strains of Klebsiella-Enterobacter were apparently more common in 1967 than in 1961 (19-1% compared with 13-2%); in part this may have been due to stricter classification in the later study, ie, some of the organisms classified in 1967 as Klebsiella-Enterobacter species were probably classified as miscellaneous bacteria in 1961. In both years, this group of organisms was largely resistant to ampicillin, possibly more so in 1967 than in 1961. The numbers of *P. aeruginosa* were slightly higher in 1967 (11-3%) than in 1961 (7-8%), and in both years these organisms were uniformly resistant to ampicillin. The incidence of Proteus species (*P. morganii*, *P. rettgeri*, and *P. vulgaris*) remained the same (approximately 2%), and fewer cultures were classified as miscellaneous bacteria in 1967 (1-3%) than in 1961 (6-6%) for the reason given above.

TETRACYCLINE RESISTANCE AT HOSPITAL 3 IN 1961 AND 1967 Most of the cultures isolated in 1967 at hospital 3 were also tested for sensitivity to tetracycline. Figure 2 shows the percentage cumulative inhibition by tetracycline of *E. coli*, *P. mirabilis*, and Klebsiella-Enterobacter isolated in 1961 and 1967. As was the case for ampicillin there was no great difference in the incidence of resistance to tetracycline of cultures isolated in 1961 and 1967. Thus 71% of the strains of *E. coli* isolated in 1967 were inhibited by 5 μg/ml tetracycline; the corresponding figure for 1961 was 72%. Similarly, 71% of the Klebsiella-Enterobacter isolated in 1967 were sensitive to tetracycline compared with 50% of 1961.
Sensitivity of Gram-negative bacilli to ampicillin after six years

strains isolated in 1961. The majority of strains of *P. mirabilis* and *Ps. aeruginosa* were insensitive to tetracycline in 1967 as was the case in 1961.

**INFECTIVE RESISTANCE AMONG AMPICILLIN-RESISTANT STRAINS OF E. coli** A total of 33 strains (out of 49 strains) isolated in 1967 resistant to 250 μg/ml ampicillin were tested for ability to transfer ampicillin resistance to the ampicillin-sensitive organism *E. coli* K12/711 NX. Of these strains, 23 (70%) transferred ampicillin resistance to the recipient strain.

Only seven of the strains of *E. coli* isolated in 1961 and found to be resistant to ampicillin were available for tests of transferable resistance. Three of these cultures had lost their resistance and were sensitive to ampicillin. The remaining four cultures were insensitive to ampicillin and transferred their resistance to *E. coli* K12/711.

**DISCUSSION**

The results presented here show that there has been no marked increase in the incidence of ampicillin resistance among Gram-negative bacilli in the hospitals in question since the introduction of this antibiotic into clinical use in 1961. In this study of bacteria isolated in 1967, and in the earlier study of organisms isolated in 1961, the majority of strains of the two most commonly isolated pathogens, namely, *E. coli* and *P. mirabilis*, were sensitive to ampicillin, while Klebsiella-Enterobacter species and *Ps. aeruginosa* were generally insensitive. A recent study in the United States involving over 4,000 isolates of Gram-negative bacteria recorded a similar distribution of sensitivity to ampicillin (Turck, 1967).

It is also of interest that the limited study of the incidence of tetracycline resistance among bacteria isolated at one hospital in 1961 and in 1967 indicated that there had been no significant change in resistance to tetracycline between 1961 and 1967. Recent studies in the USA (Bulger, Roberts, and Sherris, 1967; Petersdorf and Turck, 1966) have also reported no appreciable increase in the resistance of Gram-negative bacilli to a variety of antibiotics between 1959 and 1965. These studies did not include ampicillin, but the results reported here indicate that ampicillin appears to be no different from other antibiotics in this respect.

These findings may appear surprising in the light of the relatively recent awareness of the ability of Gram-negative bacteria to transfer antibiotic resistance to other bacteria, and subsequent speculation regarding the possibility of a rapid increase in the incidence of antibiotic resistance among Gram-negative bacteria. Our results confirm that the majority of resistant strains of *E. coli* isolated in 1967 were able to transfer ampicillin resistance *in vitro* to a suitable ampicillin-sensitive recipient strain. However, we were also able to demonstrate transfer of ampicillin resistance from four strains of *E. coli* isolated in 1961 soon after ampicillin became available for clinical use. It is a possibility therefore that the ampicillin resistance of certain Gram-negative bacilli has always been largely associated with transferable resistance, and that it is not.
necessarily a relatively new phenomenon. Unfortunately, only a limited number of bacteria isolated in the early 1960s were available to us, so we can draw no conclusions as to whether there has been any change in the incidence of strains of *E. coli* carrying R factors.

As R factors have evidently been present in Gram-negative bacilli over a relatively long period of time, and as ampicillin resistance can be readily transferred *in vitro*, it may be asked why there has not been an obvious increase in the incidence of ampicillin resistance among Gram-negative bacteria. There are various possibilities, including factors *in vivo* which affect the efficiency of transfer, incompatability between bacteria, and spontaneous loss of R factors. Whatever the reason, it is encouraging that the results reported here show no evidence of increased resistance to ampicillin among Gram-negative bacilli after six years' clinical usage.

We are grateful to Dr J. Harding of the West Middlesex Hospital, Dr J. P. Mackey of Redhill General Hospital, Dr M. Ridley of St Thomas' Hospital, and Dr R. E. M. Thompson, Middlesex Hospital, for kindly providing the cultures described here.

It is a pleasure to thank Mrs Eleanor Fairclough and Miss Christine Goater for skilled technical assistance, and Dr G. N. Rolinson for much helpful advice and criticism.
