than 36 weeks, separately or together, are of serious import has been confirmed and amplified by recent studies. During the last six weeks of gestation the foetus grows rapidly, but the placenta does not. The most important measure of placental function is thus the continuing growth of the foetus. Purely placental parameters would be useful if their variation were to precede demonstrable foetal damage. A number have been studied.

For several years we have used output of oestriol in 24 hr urine. This substance is finally elaborated by trophoblastic enzymes from dehydroepiandrosterone produced in the foetal suprarenal. Examples of the use of this to foretell slow growth of the foetus will be given and some pitfalls discussed, also its significance in conditions inimical to the foetus such as maternal hypertension or pre-eclamptic toxemia.

More recently we have tried to use the output of oxytocinase (aminopepsidase) produced by trophoblast alone. A series is presented to confirm norms for this and to compare it with oestriol output in complicated pregnancies. The mean level of oxytocinase output varies widely from case to case, so it is even more important to establish a trend over several weeks than for oestriol. Since foetal tissues are not involved, early trouble in the foetus is not revealed, but what can be interpreted as early placental failure has been demonstrated. As in all similar recent studies this is often unconfirmed since, if in doubt, the obstetrician may terminate pregnancy as soon as the foetus is mature enough to risk this and the biochemistry is only one factor in making his decision.

Trypsin and Chymotrypsin Determinations in Human Duodenal Aspirate under the Influence of Continuous Secretin-pancreozymin Stimulation as an Aid in the Diagnosis of Pancreatic Disease

D. M. GOLDBERG AND K. G. WORMSLEY (Sheffield)

The output of trypsin and chymotrypsin was measured in the duodenal aspirate of 46 patients free of known pancreatic disease or with normal pancreatic function as defined by volume, bicarbonate, and amylase response. The data from this group were compared with those obtained in 16 patients with objectively defined pancreatic disease and three patients with gastric ulcer and defective pancreatic function. In all, 150 tests were conducted, most subjects having their enzyme output measured under different regimes of stimulation, all hormones being given by continuous intravenous infusion and results expressed as milligrams enzyme per 30 minutes.

With all pancreatic tests, 0-25 units secretin/kg/hour was used to promote background flow. Insufficient data were obtained to allow evaluation of dose rates of 8 units pancreozymin/kg/hour and 2 units secretin/kg/hour. Some overlap between the two groups was found when 4 units pancreozymin/kg/hour was used, but separation was almost complete when the dose of pancreozymin was raised to 16 units/kg/hour. Better discrimination was achieved with trypsin than with chymotrypsin, although the occasional case in the second group gave low values for the latter only with some forms of stimulation.

It is recommended that for routine purposes trypsin be measured during infusion of 0-25 units secretin and 4 units pancreozymin/kg/hour. Under these conditions an output > 100 mg/30 minutes indicates normal pancreatic function and <50 mg abnormal pancreatic function. Where intermediate values are obtained, the dose of pancreozymin should be increased to 16 units/kg, and it may be worth while to measure chymotrypsin output as well in order to define the status of the patient more precisely.

The Effect of Instant Cirrhosis on Rat Serum Proteins

C. H. W. HORNE AND R. N. MACSWEEN (Glasgow)

Cirrhosis of the liver is known to be accompanied by marked alterations in the levels of serum proteins. Only in experimental cirrhosis, however, is there a ready opportunity to study serum protein levels before, during, and after the production of cirrhosis.

Cirrhosis was produced in rats using the method of McLean, McLean, and Sutton (1969). Serum samples were obtained at weekly intervals before, during, and after treatment with carbon tetra-chloride and sodium phenobarbitone, and also from animals treated with either preparation alone. Using a radial immunodiffusion technique the levels of four serum proteins, namely, albumin, slow α1-globulin, transferrin, and γ-globulin, were determined and the concentrations expressed as a percentage of a pooled normal rat serum sample. All animals were necropsied and macroscopic and microscopic proof of the presence or absence of cirrhosis was obtained. Striking alterations in the levels of all four serum proteins were observed. The significance of these findings was discussed.

Effect of Severe Hypoxia on DNA-labelling Pattern of Blood Eosinophils

G. HUDSON AND K. CHIN (Department of Haematology, University of Sheffield)

The emergence pattern of DNA-labelled eosinophil granulocytes into the circulation following administration of tryptophan thymidine has been used to follow up and earlier finding that for the first week or more of exposure to severe hypoxia, guinea-pigs show a marked peripheral eosinophilia accompanied by depletion of eosinophil numbers in the bone marrow.

Intraperitoneal injections of tryptophan thymidine in doses of 1 microcurie per gram of body weight were given to guinea-pigs of approximately 400g body weight at two-hour intervals over eight hours. At intervals of 12hr over the period of 36-180hr after the first injection, blood smears were taken and prepared for autoradiography. In four animals normal conditions were maintained throughout. Six animals were similarly maintained but at a barometric pressure of about 3.5 torr (equivalent to that at 20,000 ft altitude); in three these hypoxia was commenced 16hr before the injections, while in three it was commenced immediately afterwards.

Significantly, labelled eosinophils were first seen in the controls at 72hr and by 156hr over 90% of blood eosinophils were labelled. In the hypoxic animals, labelled eosinophils were detected at 36hr; thereafter, the percentage of labelled cells in the blood was significantly higher than in the controls until 120 hours. There was no evidence of a difference in labelling pattern between animals in which hypoxia was commenced before or after the injections. The results are consistent with a reduction in the minimum transit time through the postmitotic pool of eosinophils in the bone marrow during the earlier stages of exposure to severe hypoxia.

Anti-cancer Organization

C. G. PANTIN (Noble's Hospital, Douglas)

There are advantages in working in an island with a small and rather static population. People cannot stray in from adjoining territory. When elsewhere one would work with samples, on the island one can...
Some Aspects of Medical Genetics in Island Populations

C. A. CLARKE (Liverpool)

The study of island populations is of considerable potential interest for the investigation of genetic problems. There may be an increase in consanguineous marriages but popular guesses as to the extent to which breeding groups on an island are closed are often wrong, and this can be checked against parish register material. Furthermore, as was found in Japan, inbreeding may not necessarily be deleterious. The pattern of congenital malformations may be different from that of the mainland and a register of these should be kept, as among other things this is a useful stimulator not only of further research but also of better social care. Again, because of genetic drift, whereby chance exercises a considerable influence on gene frequencies, blood group distributions may be unusual and unfavourable mutations persist in isolated communities. These factors will be discussed in relation to the Isle of Man.

Genetics Survey of the Manx

R. J. MITCHELL (Department of Anthropology, University of Durham)

In recent years physical anthropologists and human biologists have carried out numerous surveys of the genetic characteristics of populations. In such a context this paper is a preliminary report on a study of genetic variability in the Manx population. Included in the survey were those individuals having three or four grandparents born on the Isle of Man. Results are given for the following unifactorial traits: most of the blood group antigenic systems, including ABO, Rhesus, Kell, Duffy, Lu, and Kp, the red blood cell isoenzymes acid phosphatase, and the plasma proteins haptoglobin and transferrin. Non-serological inherited factors such as phenylthiocarbamide testing are also reported upon.

For some of the serological factors comparisons were made between blood donor and non-blood donor samples. Moreover the incidence of the genetic features was compared with those found in contiguous areas of Britain, particularly south west Scotland and Cumberland.

Mention is made of previous anthropological studies of the Island's population and their main findings. All previous work was of an anthropometric rather than serological nature. One aim of the present study is to discover whether genetic factors complement the variability in the Manx population found in the previous studies.

A very brief account of the main periods occurring in the Island's history is given because of its possible use in helping to interpret the results of the present survey.

Erythroblastosis Foetalis

A. E. CLAIREAUX (Department of Morbid Anatomy, Hospital for Sick Children, London)

Erythroblastosis foetalis (haemolytic disease of the newborn) is an important, if decreasing cause, of perinatal death. Results obtained during the perinatal mortality survey (1958) (Claireaux, 1963) showed that it was responsible for 4-0% of all perinatal deaths and the incidence was 1-4 per 1,000 live and stillbirths.

The final results of a similar study, British births (1970), are not yet available but preliminary evaluation of postmortem material shows that it is still a factor in perinatal death but the incidence is probably lower than in 1958.

Erythroblastosis foetalis was a term coined in 1933 to include the three main types of disease: (a) hydrops foetalis; (b) icterus gravis neonatorum; (c) congenital haemolytic anaemia. This last is not to be confused with congenital spherocytosis. Hydrops foetalis was the most severe form of the disease and usually resulted in a stillbirth or in the delivery of a moribund infant. Icterus gravis was, if untreated, also likely to have a fatal termination and the infant succumbed as a result of brain damage (kerinicterus). The remaining cases, much less severe and seldom fatal, were clinically regarded as examples of haemolytic anaemia. The clinical features of the disease and the pathological changes in fatal cases were known some considerable time before the discovery of the Rhesus blood groups (1940). It was only then that it became clear the condition resulted from iso-immunization of the mother by a blood group she did not possess.

The Role of RH Antibodies in Causing Haemolytic Disease of the Newborn and in Preventing It

P. L. MOLLISON (Department of Haematology, St Mary's Hospital Medical School, London)

HAEMOLYTIC DISEASE OF THE NEWBORN

The relation between the amount of anti-Rh on the red cells of an Rh-positive infant and the severity of the haemolytic process is not very close; one reason may be the varying ability of different examples of anti-Rh to bring about red cell destruction.

In haemolytic disease of the newborn, the concentration of anti-Rh in the plasma of the Rh-positive infant is always very much lower than that in the mother's plasma, emphasizing that the relatively slow transfer of IgG across the placenta plays a crucial role in mitigating the severity of the damage. Because of this slow transfer, it is quite safe to give injections of the order of 200 mg anti-Rh to Rh-negative women who are pregnant with an Rh-positive foetus. Incidentally, even if such a dose is accidently injected into a newborn Rh-negative infant, it causes only very mild haemolytic disease.

PRIMARY RH IMMUNIZATION

A single injection of Rh-positive red cells induces primary immunization in about 65% of Rh-negative subjects. With a relatively large dose (200 ml cells), anti-Rh is as a rule readily detectable three to six
