A simple, inexpensive gel filtration technique for use in diagnostic serology

J. R. PATTISON AND JENNIFER E. MACE From the Department of Virology, The School of Pathology, The Middlesex Hospital Medical School, London

Previously described methods (Best, Banatvala, and Watson, 1969; Gupta, Peterson, Stout, and Murphy, 1971; Haire and Hadden, 1972) for the separation of IgM and IgG as applied in diagnostic serology all involve at least moderate capital expenditure and/or a skilled, highly standardized technique. In investigating gel filtration techniques in order to define a simple, inexpensive, robust technique for the fractionation of human sera the following system has been devised. The basic technique has been applied in this laboratory for the past five years in the serological diagnosis of recent rubella and no difficulties in interpretation of the results have been encountered.

Methods

APPARATUS
The cheapest automatic fraction collector available is the Boulting fraction collector (James A. Jobling, Laboratory Division, Stone, Staffs). The remainder of the system has been designed around this fraction collector so as to achieve the desired separation of IgM and IgG when collecting 4-5 ml fractions. The most convenient column for this has been found to be the 500 × 20 mm Quickfit chromatographic column (Baird and Tatlock, Romford, Essex) packed to a length of 50 to 52 cm with Sephadex G-200 (Pharmacia, Uppsala, Sweden) suspended in Nairn PBS (Nairn, 1964) plus 0-02% sodium azide (PBS-NA). The remainder of the apparatus consists of a constant level solvent reservoir with an airtight feed to the top of the column. As illustrated this consists of a transfusion bottle, an intravenous infusion set with the filter removed, and a serum needle passing through a rubber bung (fig 1).

Fig. 1 The apparatus.

FRACTIONATION OF SERA
The technique is illustrated by its application to the serological diagnosis of recent rubella. Taking care not to disturb the gel itself, layer onto the top surface of the gel a sample (determined as one tenth the fraction volume, ie, 0-4-0-5 ml) of serum pretreated with MnCl₂/heparin/50% pigeon RBCs (Dold and Northrop, 1968). Elute the serum sample at a rate of not more than 20 ml/hr. After 40 fractions have been collected the column is cleared for the next run, and with such a system a single column will perform 30-50 fractionations. Rubella haemagglutination inhibition (HAI) tests are performed on the appropriate fractions (for methods of selec-
tion of these see results section) from a dilution of 1 in 1 to 1 in 64 with a control lacking antigen for each fraction. A microtitre system was used involving the mixture of 4HA Units with serial doubling dilution of the eluted fractions using 0.4% bovine albumin-borate saline (Clarke and Casals, 1958) as both antigen and fraction diluent. Virus/fraction mixtures were incubated overnight before the addition of 0.25% pigeon RBCs (diluted in bovine albumin-DGV, Stewart, Parkman, Hopps, Douglas, Hamilton, and Meyer, 1967) as indicator.

Results

The system has been designed so that by titrating the appropriate 12 fractions the entire distribution of immunoglobulins will be covered (fig 2). These 12 fractions are most easily found as follows. Locate the first fraction which after vigorous shaking carries a persistent head of froth (in practice this should be fraction 7, 8, 9, or 10). Choose two fractions before this as the first fraction for rubella HAI titration and titrate this and the subsequent 11 fractions across a microtitre plate.

Fig. 2 Elution patterns of protein. Five ml fractions were eluted from a column of Sephadex G-200 as described and protein content measured as follows:
(a) continuous monitoring OD 280 μm with Uvicord II (LKB Instruments Ltd)
(b) measured, after concentration, in Immunoplates (Hyland Laboratories Inc)
(c) Froth persisting at 10 sec after vigorous shaking for three to four seconds.

Figure 3 illustrates the various patterns of rubella HAI activity that may be found with a particular column when collecting 5 ml samples. Figure 3A shows the result of fractionating a high titre serum in which all the rubella HAI activity is in the IgG containing fractions. Activity occurring in these early fractions, being IgM, is only found in sera taken after recent rubella. The relative proportions of IgM and IgG activity in early convalescent sera is shown in fig 3 for sera taken two to three days (fig 3B), four to six days (fig 3C), 10-14 days (fig 3D), and four to six weeks (fig 3E) after the onset of the rubella rash. All these sera are from patients in whom rubella was diagnosed on the basis of rising titres.

An internal control of each fractionation is achieved by comparing the HAI activity appearing in the fractions (column recovery) with the reciprocal titre of the serum before gel filtration (straight titre). There should be less than one doubling dilution

Fig. 3 Patterns of rubella HAI activity in fractionated sera. Five ml fractions were eluted from the same columns used to acquire the data in figure 2. For further explanation see text.
difference between the two. Fractions are diluted 1
in 20 by comparison with the original serum there-
fore the column recovery is obtained by adding
together the reciprocal titres of all the fractions and
multiplying by 20.

Comment

The method is as inexpensive as possible granted
that an automatic fraction collector is used. The
total capital cost, assuming that one is already per-
forming HAI tests is £50. The technique has been
made as simple as possible by removing all strictly
unnecessary steps. Accordingly interpretation of
results has been based on an appreciation of the
overall pattern of HAI activity within the IgM and
IgG fractions so that no undue emphasis is placed
one anyone titration. Of course better separation can
be achieved by using longer columns of gel but this
inevitably increases the cost and technical difficulties.

Just as variations in any of the parameters of
rubella HAI tests have been shown to alter the
results obtained (Schmidt and Lennette, 1970), so do
any changes in the method of fractionation of sera.
It is emphasized that each of these variables has
been investigated and that the detailed procedures
described have been selected so that the method
remains simple but gives accurate results without
difficulties of interpretation. Although the use of the
method has been illustrated only for rubella serology,
it could be applied to any serological test which will
accept an initial serum dilution of 1 in 20 and is not
affected by the presence of Nairn PBS plus 0-02% sodium azide.

Technical methods

Wet ashing using a closed system

GEORGE P. LEWIS AND LINDA L. COULHIN From the
Section of Clinical Pharmacology, Boston Veterans
Administration Hospital and Tufts University School
of Medicine, Boston, Massachusetts

Wet ashing procedures are being used more exten-
sively because of the increased interest in the bio-
logical role of trace metals. The standard procedures,
using fuming nitric acid, or mixtures of concentrated
acids are normally carried out within a laboratory
hood, the acid fumes being vented through the hood’s
exhaust duct. To obtain adequate digestion, such
techniques require the addition of several aliquots of
acid. When large numbers of samples are being pre-
pared, a considerable quantity of acid can be used
in one day. These ‘open’ standard procedures lead to
the emission of highly acid fumes into the ambient
atmosphere, result in marked erosion of the hood’s
exhaust system, and can give rise to unacceptable
levels of acid fume in the laboratory air. In order to
overcome these objections, a ‘closed’ wet ashing
system has been used in this laboratory during the
past two years for the preparation of cadaver tissue
samples for atomic absorption spectrophotometry
(Lewis, Jusko, Coulhlin, and Hartz, 1972a and b).

Method

Samples (kidneys 0-5 g, liver 2 g, lungs 4 g) are each
placed in a 100 ml Erlenmeyer flask. Each flask is
fitted to a Stark-Dean distilling trap of 10 ml
capacity. Above the receiver is fitted a water-cooled
condenser. All components have ground glass
joints. The whole is then placed over a hot plate
sited within a laboratory hood. Initially, the hot
plate is set at 250°C, and the acid and sample are
allowed to simmer gently for two hours with the
hood exhaust fan on. The circulation of air around
the Erlenmeyer flask prevents distillation of the acid
into the trap. After this time, when the tissue has
been completely solubilized and digested, the hood
fan is turned off, and the hot plate is turned up to
350°C. The acid then refluxes into the trap over 20
to 30 minutes. When the volume of digest is reduced
to 0.5 to 1.0 ml, heating is stopped by placing an
asbestos pad between the hot plate and the Erlen-
meyer flask. Following cooling, 15 ml of distilled
water is added to the digest, and the pH adjusted by
titrations to 3.5 with concentrated ammonium
