Fat embolism in sickle cell disease

R. M. HUTCHINSON, M. V. MERRICK, AND J. M. WHITE

From the Departments of Haematology and Radiology, Hammersmith Hospital, London

SYNOPSIS  Fat embolism is a known complication of marrow infarction in patients with sickle cell disease (Hb S/S and Hb S/C) disease. It should be considered in sickle cell crisis when there is deterioration in respiratory function, a fall in arterial PO₂, a normoblastaeam, and a thrombocytopenia in the peripheral blood. We now report a patient in whom the diagnosis was confirmed in life by identifying fat in the sputum, demonstrating disseminated intravascular coagulation, and using a double isotope technique to distinguish recent from old marrow infarction. Use of these features enabled an early diagnosis to be made which led to a successful outcome in a potentially fatal condition.

Fat embolism is a well known complication of bone marrow infarction in patients with Hb S/S and Hb S/C disease (Charache and Page, 1967; Brown, 1972). This condition can progress rapidly to a fatal conclusion unless early diagnosis and treatment is initiated (Rywilin, Black, and Werner, 1963; Hendrickse and Watson Williams, 1966). In the case reported the diagnosis of pulmonary fat embolism was suspected on clinical and haematological grounds. Early confirmation was made by finding fat globules in the sputum, a low P₉₀ and the presence of disseminated intravascular coagulation.

A whole body scan following the intravenous injection of ³⁰Tc⁺⁺ sulphur colloid confirmed that there was extensive bone marrow infarction, demonstrated the extent of the infarction, and indicated the most promising sites for biopsy.

Case Summary

The patient was a 19-year-old West Indian female known to suffer from sickle cell anaemia (Hb S 88%, Hb F 10%, Hb A₂ 2%). She was admitted to hospital after a 12-day history of an influenzal-like illness associated with bronchitis, increasing lethargy, deepening jaundice, and dyspnoea. On examination she was febrile (temperature 99.5°F) but no abnormal chest signs were noted. The spleen was not palpable. The investigations showed Hb 7-2 g/100 ml (it had previously been 10-0 g/100 ml); WBC 14 000/μl, with 70% neutrophils; platelets 340 000/μl. A chest radiograph was normal. Before admission she had received ampicillin 250 mg qds for five days. She was treated with Septrin 2 tablets bd and given fluids orally, 3-4 l daily.

Over the next 48 hr her condition deteriorated, with increasing pyrexia (temperature 100-104°F), dyspnoea. Generalized crepitation appeared over the lung fields as well as signs of consolidation of the right lower lobe. She became restless, irritable, and developed pain in the mandible and right femur and anaesthesia over the area supplied by the mental branches of the inferior dental nerve. Her Hb had fallen to 5-2 g/100 ml, platelets to 100 000/μl, and the WBC had risen to 45 000/μl (fig 1). Most of the nucleated cells in the blood were normoblasts, none having been seen in previous films. Myelocytes and megakaryocytes were also present. Her arterial PO₂ was 62 mm Hg. At this time a diagnosis of marrow infarction, fat embolism, and disseminated intravascular coagulation was considered because of the association of the pulmonary findings, thrombocytopena, and normoblastaeam. The diagnosis was confirmed 24 hr later, when fat both as free globules and inside histiocytes was found in the sputum. Evidence suggestive of intravascular coagulation was the finding that the fibrin degradation products were elevated to 16 mg/ml. During this period she was treated with continuous oxygen (60%), on which her arterial PO₂ rose to 120 mm Hg, and she was transfused with 3 units of blood. Her clinical status improved rapidly; although the chest signs responded slowly.

A whole body scan of the bone marrow was performed, starting 10 minutes after the iv injection of 6 mCi of ³⁰Tc⁺⁺ sulphur colloid (Stern, McAfee,
Fat embolism in sickle cell disease

and Subramanian, 1966), using an Ohio nuclear model 84 whole body scanner fitted with twin 5 in. diameter × 2 in. thick thallium-activated sodium iodide detectors, arranged to make simultaneous anterior and posterior scans. The findings were a generalized extension of marrow, but with the normal symmetry disturbed by multiple defects in the skull, left humerus, lumbar spine, pelvis, both femora, and both tibia (fig 2). Biopsy from the right ilium (arrowed) revealed only necrotic, pyknotic cells with no normal marrow. These findings confirmed that the infarction was recent. A further whole body scan two weeks later carried out one hour after the iv administration of 2 mCi of $^{18}$F revealed increased activity in the areas in which recent infarction was suspected. This was evidence of increased bone turnover associated with replacement of infarcted tissue, and thus distinguished filling defects in the marrow due to recent infarction from those of longer duration (Merrick, 1973).

She was transfused with 3 more units of blood until her Hb had risen to 12 g/100 ml (the concentration of Hb S was 15 % at this time). The signs in the chest gradually disappeared and the platelet count rose with the disappearance of normoblasts and a decrease in the fibrin degradation products from the blood. She was discharged two weeks after admission.

Four weeks later she was well and the pain in the right femur had disappeared, though the anaesthesia over the jaw was still present. The haemoglobin was 10·2 g/100 ml, WBC 5 000/µl, and platelet count 370 000/µl. A repeat bone marrow scan showed active

Fig 2 Bone marrow scan using technetium sulphur colloid. Note the absence of radioactivity over the right pelvis and femur. The arrow indicates the approximate site of the marrow biopsy.

Fig 1 The haematological indices of the patient during her illness. Attention is drawn to the decrease in Hb level and platelet count associated with a marked increase in circulating normoblasts in the peripheral blood.
marrow in the pelvis and right femur with a more uniform distribution of the marrow in other sites; however, a bone marrow biopsy of the right iliac crest was not successful.

Discussion

As far as we are aware there have been no previous reports of patients with sickle cell anaemia in whom the diagnosis of fat embolism has been confirmed in life. At necropsy these patients had fat and marrow emboli in the small capillaries of the brain, lungs, and kidneys (Shelley and Curtis, 1958; Wertham, Mitchell, and Angrist, 1942). In none of the cases was the sputum stained for fat before death. There are no detailed reports of the haematological findings of these patients before death but in four of the cases a normoblastaemia in the peripheral blood was noted. In one report a thrombocytopenia of 82,000/μl was found (Ober et al., 1959). Evidence of disseminated intravascular coagulation was not sought. However, in our case evidence of disseminated intravascular coagulation was a strong indication that thromboplastic material was present in the circulation.

There are a number of possible isotopes which can be used to delineate the marrow. \(^{55}\)Fe, the most logical, is however, not readily available but in most conditions the reticuloendothelial and haemopoietic functions of the marrow have the same spatial distribution (Kniseley, 1972) so that any of the readily available radioactive colloids may be used. However, 80-90% of the injected dose is taken up by the liver and spleen. This makes it impossible to examine those regions of the marrow which lie close to these organs, such as the sternum, lower ribs, and upper lumbar spine. These areas can be visualized with alternate radiopharmaceuticals such as transferrin labelled with Indium \(^{111}\)In or Dysprosium \(^{157}\)Dy gluconate.

There are few previously reported cases of marrow scanning in sickle cell disease and in none was any change observed between the first and subsequent scans (Alavi, Bond, Kuhl, and Creech, 1972; Denardo, Hammel, Lewis, and Denardo, 1972). The finding in the present case of filling defects on the first scan, some of which were not present two months later, is confirmation that infarcted marrow may regenerate. Bone scans performed with \(^{18}\)F indicate regions of new bone formation associated with the removal of infarcted trabecular bone along with its infarcted marrow. These changes will not be detectable radiologically. It is anticipated that \(^{85}\)Sr should be as effective as \(^{18}\)F.

Double scanning, with colloid and \(^{18}\)F, is thus more specific than the colloid scan alone, but there is no direct evidence how long it takes for the \(^{18}\)F scan to become abnormal in this condition. Extrapolating from the observations made following trauma, the likely period is one to two weeks.

The apparent high mortality associated with fat embolism in patients with Hb S/S and Hb S/C disease contrasts with the low mortality when fat embolism occurs from bone trauma in patients with Hb A. It is likely that the two most serious factors in fat embolism in both groups are hypoxia and intravascular coagulation (Bradford, Foster, and Nossel, 1970) and both would initiate a vicious circle of further sickling and infarction in patients with sickle cell syndromes. The degree of hypoxia is particularly important, since in vivo all erythrocytes containing only Hb S will probably sickle if the arterial \(PO_2\) falls below 50 mm Hg.

We suggest that fat embolism should always be considered in patients with a sickle cell crisis, especially when it is accompanied by rapidly deteriorating respiratory signs, a fall in arterial \(PO_2\), the presence of numerous circulating normoblasts in the peripheral blood, and thrombocytopenia. Evidence of disseminated intravascular coagulation should be looked for. We believe that heparin therapy (as suggested by Hendrikse and Watson-Williams, 1966) in addition to continuous oxygen and rapid transfusion will reverse this potentially fatal condition.

One of us (M.V.M.) is in receipt of an MRC grant (number G. 689).
