SYNOPSIS A number of conditions have been assessed for the collection of serum samples for the measurement of fibrin(ogen) degradation products using a radioimmunoassay for degradation fragment E, which permits precise quantitation of differences. Blood should be collected using minimal venous occlusion into glass tubes containing 10 mg/ml of epsilon amino caproic acid and allowed to clot at 4 to 20°C for at least 4 hours before centrifugation. The serum may be stored at 4 or −20°C. Samples from patients receiving anticoagulant therapy should be treated with 10 IU of thrombin per ml.

Serum levels of fibrin(ogen) degradation products (FDP) have been used since 1961 (Ferreira and Murat, 1961) in the diagnosis and treatment of both disseminated and local intravascular coagulation. Fibrinogen and fibrin are degraded by the fibrinolytic enzyme system to produce a heterogeneous series of degradation products of decreasing molecular weight: only the earliest products in the chain retain the ability to clot (Marder et al., 1969). When FDP levels are measured in serum only the non-clottable molecules will be present, all others having been removed during coagulation. In preparing serum samples for the measurement of FDP it is essential to ensure that coagulation is complete; if it is not, the measured FDP levels will be falsely raised due to the persistence of clottable molecules. It is equally important to prevent activation of the fibrinolytic enzyme system during coagulation as this could also lead to an increase in levels in vitro. With these problems in mind, several workers have suggested conditions for the collection and preparation of serum samples for FDP determinations (table I).

FDP levels can be measured by a variety of immunological techniques including haemagglutination inhibition (Merskey et al., 1966), latex particle agglutination (Allington, 1971), immuno-electrophoresis (Niléhn and Nilsson, 1964), and radioimmunoassay (Gordon et al., 1973; 1975, Plow and Edgington, 1973). The radioimmunoassay method has the advantages of high sensitivity and precision, and is thus well suited to the study of variables in sample collection and preparation. In the present study a number of these variables have been examined in detail.

Material and Methods

All blood samples were collected into plastic syringes using minimal venous occlusion. The samples were aliquoted into glass tubes containing either (1) no additive, (2) 10 mg/ml amino caproic acid solution (EACA, Kabi Pharmaceuticals), (3) 250 Kallikrein inactivator units/ml aprotinin solution (Trasylol, Bayer Pharmaceuticals), (4) 10 mg/ml freeze-dried soybean trypsin inhibitor and 10 NIH units/ml thrombin (Wellcome Reagents), (5) 10 NIH units/ml of freshly suspended thrombin (Parke Davis Ltd) and 10 mg/ml EACA, (6) as (5) but stored at 20°C for 7 days, (7) as (5) but freeze-dried before use. Thrombin was also added to the serum after separation. Incubation times of whole blood from 4 to 96 hours were studied at 4°C, and temperatures from 4°C to 37°C were studied for a fixed time of 24 hours. Serum was separated by centrifugation at 1500 g for 45 minutes and stored at either 4°C or −20°C for up to 10 days. In one set of experiments the coagulation...

Table I  Methods of collection of serum samples for FDP assays

ns = not stated

process was interrupted in the presence of EACA (10 mg/ml) by the addition of heparin 25 IU/ml (Weddel Pharmaceuticals) and immediate separation of the blood.

The FgE radioimmunoassay was performed as described previously (Gordon et al, 1975a). All the samples were assayed in duplicate at a 1:10 dilution, and EACA, aprotinin, soybean trypsin inhibitor, heparin, and thrombin were all tested for their ability to inhibit antigen-antibody binding. Three quality control sera were included in each assay performed, and comparative samples were always assayed in the same run. Results were compared by linear least squares regression analysis.

Results

When the coagulation process was interrupted by the addition of heparin there was a progressive decrease in FgE immunoreactive material in blood beginning within 10 minutes of exposure to glass by 20°C; by 30 minutes only 0.4% of the initial activity was present at both 4°C and room temperature, and a further decline to 0.1% occurred by 2 hours (fig 1). Incubation of whole blood at 37°C in the absence of EACA resulted in an increase in FgE reactive material within 4 hours (fig 2). The results of the other studies are summarized in table II; incubation for longer than 4 hours at 4°C had no effect on FgE levels; at 37°C there was a significant rise at 24 hours. This rise was greater in the presence of aprotinin, and an even greater increase was seen with soybean trypsin inhibitor in spite of the presence of thrombin (fig 3). The addition of freshly suspended thrombin, either before (fig 4) or after centrifugation, caused an equal and significant reduction in FgE levels. The addition of

Discussion

There is only one previous study in which the optimal conditions for the collection of serum samples for FDP assay have been examined (Merskey et al, 1972). In the present investigation a variety of conditions have been evaluated in detail. To be of diagnostic value FDP levels in serum should reflect circulating degradation products and not an artefact due to either incomplete fibrinogen conversion or to activation of the fibrinolytic system. Activation of the coagulation system in vitro by contact with glass will activate the fibrinolytic enzyme plasmin. The extent of plasmin action will depend on the degree of activation and the time and temperature exposure. Although naturally occurring plasmin inhibitors are found in blood, plasmin is selectively concentrated within the fibrin mesh and may escape the effects of these inhibitors (McNicol and Douglas, 1972). In addition to plasmin, a number of other proteases including trypsin are able to degrade the fibrin molecule (Latallo et al, 1971). However, the results described here would indicate that in vitro degradation of fibrin is mainly due to plasmin. Thus EACA, which is a specific plasmin inhibitor (Brockway and Castellino, 1971), almost completely inhibited FDP formation in vitro, whereas less specific protease inhibitors (aprotinin and soybean trypsin inhibitor) produced only partial inhibition.

Activation of the fibrinolytic system occurs despite the presence of EACA when whole blood is incubated at 37°C for 24 hours. The presence of fibrin is essential since the effect is not seen with separated serum, as previously shown by Merskey and his coworkers (1972).

Optimal activation of the contact factors (XI, XII) of the coagulation system in vitro depends on a number of factors including time, temperature, calcium concentrations, and glass in contact with the blood (Nossel, 1972). In the absence of thrombin, coagulation is 96% complete within 10 minutes at 20°C and 99.9% complete within 60-90 minutes at both 4°C and −20°C. The addition of freshly prepared thrombin produces significant reduction in the final concentration of FDP measured, and it seems likely that the concentration of endogenous thrombin produced in vitro is insufficient to coagulate all the clottable fibrinogen molecules. Observations on the nature of FDP in normal subjects (Divall, 1974) suggest that the material measured with immunological techniques consists mainly of soluble fibrin polymer of molecular weight greater than that of fibrinogen. These polymers contain partly degraded fibrinogen as judged by the ability of normal serum to cross react in the radioimmunoassay for the neoantigen of fragment D which is specific for the degradation products of fibrin(ogen) (Gordon et al, 1975b). The presence of additional exogenous thrombin probably completes the coagulation of these partially degraded, high molecular weight fragments, whether added before or after separation of the serum. However, from the point of view of routine use, the disadvantage of thrombin addition is that the solution cannot be freeze-dried nor can it be stored at room temperature. The use of thrombin should probably be confined to those patients on anticoagulant therapy. In the present study, the findings of Merskey and his coworkers (1972) that thrombin will cause an elevation of FDP levels has not been confirmed. This discrepancy may perhaps be explained by the lack of sensitivity and precision of the tanned red cell haemagglutination inhibition assay used in the previous study.

Venous occlusion has been shown previously to cause a rise in the serum levels of FgE related to the rise in haematocrit and therefore due to haemoconcentration (Butler et al, 1975).

In conclusion, the optimum procedure for the collection of blood for FDP assay is as follows: samples should be taken using minimal venous occlusion into glass tubes containing 10 mg/ml of EACA and allowed to clot at 4°C to 20°C for at least 4 hours before centrifugation. The serum may be stored at either 4°C or −20°C. Samples
from patients receiving anticoagulant therapy should be treated with 10 units of thrombin per ml of blood.
