Identification of Gram-negative bacteria in histological sections using Sandiford’s counterstain

R. E. LEAVER, B. J. EVANS, AND B. CORRIN Department of Morbid Anatomy, St. Thomas’s Hospital Medical School, London SE1 7EH

There exist many methods for the application of the Gram stain to histological sections, and with all of them there is generally no difficulty in recognising Gram-positive organisms. However, with most of the well-recognised methods Gram-negative bacteria are difficult to distinguish from the background. Twort’s method distinguishes Gram-negative bacteria from the background but is relatively time-consuming (Cook, 1974), and we therefore turned our attention to Sandiford’s modification of the Gram stain (Cruikshank et al., 1975). Sandiford’s counter stain was designed for use with bacteriological smears but appeared eminently suitable for applying to paraffin sections. In brief, the modification consists of staining bacteria which are not Gram-positive with pyronin and using malachite green as a counterstain. The resultant black and red organisms (Gram-positive and -negative respectively) both contrast well with the blue-green background and are easily recognisable. We have used this method for the last five years and have found it most helpful in the recognition of Gram-negative bacteria. A comparison of Twort’s and Sandiford’s modifications of the Gram stain shows that the results are virtually indistinguishable, but we prefer the Sandiford method because it is quicker. Recently, Sowter and McGee (1976) have described a Gram-methyl green-pyronin-light green method which gives results comparable to the Gram-Sandiford technique but again the latter stain acts much more quickly. No doubt some histopathology laboratories already use the Sandiford modification but we are unable to find any description of it in the standard histology manuals and believe that it deserves wider recognition.

Method

1 Dewax in xylol
2 Absolute alcohol rinse
3 Distilled water rinse
4 1% aqueous crystal violet or methyl violet, 3 min
5 Rinse in tap water

Received for publication 17 November 1976

**Sandiford’s stain**

- Malachite green 0.05 g
- Pyronin 0.15 g
- Distilled water 100 ml

**Result**

Gram-positive organisms are purple-black, Gram-negative organisms red, and background blue-green (Figure).

Figure Pseudomonas aeruginosa pneumonia showing the characteristic invasion of an arterial wall by numerous Gram-negative bacilli. Individual bacteria can be recognised in the surrounding tissues. Gram with Sandiford counterstain × 225.

Demonstration of bacterial capsular polysaccharide in CSF by counter immunoelectrophoresis

The demonstration of bacterial capsular polysaccharide in cerebrospinal fluid (CSF) by counter immunoelectrophoresis (CIE) has provided a useful addition to the usual diagnostic tests (Greenwood et al., 1971; Coonrod and Rytel, 1972; Higashi et al., 1974; Myhre, 1974), particularly in patients who have been given antibiotics. Unfortunately, with group B meningococci the method often fails because of the poor precipitating activity of commercially available antisera (Tobin and Jones 1972). However, group B meningococci share a capsular antigen with Escherichia coli K1 (McCracken, 1976) which can be used as a control to validate the activity of antimeningococcal group B antisera.

Equine group B meningococcal antiserum is available on request from Dr. John B. Robbins of the Department of Health and Welfare, USA1 but, according to the accompanying instructions, the antiserum is unsatisfactory when CIE is carried out using agarose as supporting media. Also, it has been found with rabbit antimeningococcal group B antiserum that reaction with E. coli K1 antigen may be apparent only when using modified electrolyte systems in CIE (Fallon and Mellmurray, 1976).

I should like to draw the attention of those who use the method that the equine globulin kindly supplied by Dr. Robbins does give precipitation (to titre) with purified K1 polysaccharide, also provided, when CIE is performed using ready prepared agarose plates (Millipore, UK) in barbitone buffer, pH 8.6, at 12 mA for one hour. Three commercially available antimeningococcal antisera (Wellcome Polyvalent A-D, Wellcome group B, and Difco Polyvalent A-D) did not form a precipitate with the K1 antigen or with a specimen of CSF from a patient with established group B meningococcal meningitis. However, dilutions of up to 1 in 8 of this CSF sample did precipitate with neat horse antiserum provided by Dr. Robbins. A sample of neat CSF (but not in dilution) from a patient with established group C meningococcal meningitis cross-reacted with the equine globulin, a finding also observed by Dr. Robbins. Therefore, long-term usage will be required to determine the absolute specificity of this equine globulin.

These preliminary findings suggest that the sensitivity of CIE for the detection of group B meningococcal antigen will be improved by using the antiserum provided by Dr. Robbins. However, in neonates CIE alone will not differentiate between E. coli K1 and group B meningococcal meningitis.

Starch serum agar—a differential medium for the isolation of Corynebacterium vaginale ('Haemophilus' vaginale)

Recently, many reports have been published on the bacteriological and clinical aspects of infection with Corynebacterium vaginale, a Gram-variable rod first isolated from the genitourinary tract by Leopold (1953). There is also increasing evidence that the organism may cause vaginitis and cervicitis in women and urethritis in men (Dunkelberg and Woolvin, 1963; Lewis et al., 1972; Åkerlund and Mårdh, 1974).

Casman's blood agar (Casman, 1947; Dukes and Gardner, 1961) is generally used for its isolation, but colonial differentiation from other genitourinary flora is often difficult. Dunkelberg's peptone starch dextrose (PSD) agar (Dunkelberg et al., 1970) gives better results but colony differentiation on the primary culture plates remains a problem. A new differential medium, starch serum agar (SS), has been devised and found to give consistent results. It's
