Determination of antibody levels to *Candida albicans* in healthy and hospitalised adults using a radioimmunoassay

SUSAN J. COBB AND D. PARRATT

From the Department of Bacteriology and Immunology, Western Infirmary, Glasgow G11 6NT, UK

**SUMMARY** A radioimmunoassay for antibody to *Candida albicans* is described. The test uses whole, killed organisms as the antigen and radiolabelled sheep anti-human globulins to quantitate different classes of antibody to *C. albicans*. The assay has been compared with an Ouchterlony precipitin method and found to be simpler, more rapid, and more sensitive than the latter. Results obtained from two groups of symptomless adults indicated that the range of antibody level was wider for a hospitalised group than for a group of blood transfusion donors, particularly in respect of IgG and IgA antibody. The reason for the increase of antibody in hospital patients was not clear but may have been related to antibiotic therapy. The difficulties in interpretation of Candida serology have therefore been re-assessed in the light of more detailed knowledge of the range and type of antibody to be expected in normal individuals.

*Candida albicans* infection presents many problems in clinical practice. Most notable of these is the distinction between serious organ infection involving, for example, the lung or oesophagus and simple colonisation of these sites. This distinction is difficult to make by cultural examination, although the demonstration of mycelial forms in the specimen or biopsy material has been regarded as an important indication of infection (Winner, 1969). Recently, it has been suggested that the demonstration of serum antibody to mycelial rather than blastospore antigens, using a fluorescent antibody method, is a simpler and more sensitive way of detecting deep tissue infection (Ho et al., 1976). Heavy colonisation of the mouth, pharynx, gut, and urinary tract by the organism is now commonly seen in patients receiving broad-spectrum antibiotics (Seelig, 1966) and the progress of the colonisation requires careful monitoring if deep tissue infection or septicaemia are to be avoided.

We here describe a radioimmunoassay (RIA) for the quantitation of antibody to *C. albicans* which is simple, accurate, and sensitive, and which has been specifically designed to enable the clinician to follow the humoral immune response during increased colonisation by the organism. In this initial communication we report the results of antibody quantitation for a group of healthy adults and for a selected group of hospitalised adults. The RIA has also been compared with the Ouchterlony double diffusion precipitin test which has, in the past, been the most widely used serological method for the diagnosis of candidiasis.

**Material and methods**

**ANTIGEN**

*C. albicans* was obtained from the throat of a healthy individual by standard cultural methods. The organism produced a positive germ tube result within three hours and showed typical streak formation on cornmeal agar after 24 hours at room temperature (20°C). A stock culture was maintained on peptone-agar slopes with periodic subculture. For antigen preparation the organism was cultured on brain-heart infusion agar for 84 hours at 37°C, the growth being harvested mechanically, suspended in 0-15 m NaCl, and killed by heating at 70°C for one hour. The yeast cells were then washed thrice with 0-15 m NaCl. After washing, a 20% (v/v) working suspension was prepared in 0-15 m NaCl.

**ANTISERA**

Sheep anti-human IgG and sheep anti-human IgA were available from laboratory stock and were checked for heavy chain specificity by testing against
chromatographically purified human IgG, IgA, and IgM using standard immunoelectrophoretic techniques. Rabbit anti-human IgM was obtained commercially (Wellcome Reagents Ltd). 200 mg anti-IgG, 60 mg anti-IgA, or 40 mg anti-IgM globulin preparations (obtained by precipitation with 36% w/v NaSO₄) were radiolabelled with 0.5-1.0 mCi iodine-125 (¹²⁵I) (IMS 30, Amersham Ltd) by the chloramine T method of McConahey and Dixon (1966). Free (non protein-bound) ¹²⁵I was separated by chromatography using Sephadex G-25 (Pharmacia Ltd).

SAMPLES OF SERUM
(A) A collection of 40 sera from blood transfusion donors in the West of Scotland was supplied by the Strathclyde Regional Blood Transfusion Unit. The age and sex of the donors were not known.

(B) Forty sera were obtained from the Haematology Department, Western Infirmary, Glasgow from inpatients who had required blood grouping and cross-matching. This group of sera was selected from patients between the ages of 18 and 65 years, and sera from seriously ill patients were not included. In the majority of instances, cross-matching had been carried out as a prelude to elective surgery.

(C) The standard serum used for RIA was a 250 ml donation from a patient recently recovered from pulmonary candidiasis. This serum was stored in 1 ml aliquots.

The amount of antibody of the different classes in the standard serum was estimated in weight units by quantitative agglutination according to the method described by Nielsen et al. (1973). After the final elution of the antibody, the quantitation of the various classes of immunoglobulin was achieved by Mancini assay using low-level Immunoplates (Hylland Ltd). The standard serum was found to contain 154 µg/ml IgG antibody, 39 µg/ml IgM antibody, and 57 µg/ml IgA antibody.

(D) Seventy-four sera were used for comparison of an Ouchterlony precipitin test and the RIA, and these were from patients in the Western Infirmary, Glasgow. The sera had been received for routine assay of candida antibody. This group included patients without any clinical evidence of candidiasis, patients with chronic mucocutaneous candidiasis, and patients with either organ infection or colonisation of multiple sites. All sera were stored at −20°C until used.

RADIOIMMUNOASSAY
The method was modified from the technique described by Nielsen et al. (1973). A standard curve was obtained in the first instance by adding aliquots of the standard serum neat and at doubling dilutions up to 1 in 16 to aliquots of C. albicans suspension, contained in 70 × 12 mm plastic tubes. After mixing, the contents were incubated for 30 minutes at room temperature and washed thrice with 0.15 M NaCl. An aliquot of radiolabelled antoglobulin (of appropriate specificity) was then added to each tube, and the incubation and washing procedures were repeated, after which the radioactivity remaining in the cell pellets was measured using an ICN Gamma gamma counter. Control tubes containing only antigen suspension and radiolabelled antoglobulin were included in the test to provide a measure of non-specific binding of the latter to the organism. From the results with the standard serum it was possible to adjust the quantities of antigen or antoglobulin to provide conditions of excess of each of these components, in the manner described by Nielsen et al. (1973). Typically, it was found that 200 µl C. albicans suspension contained an excess of antigen for 100 µl of the standard serum, and an excess of antoglobulin was contained in 125 µl algG, 75 µl algA, or 75 µl algM solution. Thereafter assays of unknown samples were performed simultaneously with assays of dilutions of the standard serum and controls, to provide a direct quantitation of the antibody content of the unknown samples. Since the antibody content of the standard serum had been calculated in weight units, it was possible to determine the weight of IgG, IgA, and IgM antibody in each test sample. Bovine serum albumin (0.1% w/v) was added to the washing solution in assays of IgM and IgA antibody to lower the non-specific binding of the antoglobulin to the organism.

OUCHTERLONY DOUBLE-DIFFUSION PRECIPITIN TEST
The antigen used was prepared from 30 ml of a 20% suspension of C. albicans obtained as for RIA (see above). The organism was disrupted by several freeze/thaw cycles or mechanically in a Braun disintegrator. After centrifugation, the supernatant was removed and concentrated to approximately 18 ml by dialysis against Carbocawx. This concentrate, neat and diluted 1 in 10, produced several precipitin arcs with sera known to have high levels of antibody to C. albicans.

The precipitin tests were performed in 1% Ion agar (Oxoid) poured to a depth of 4 mm in plastic Petri dishes. A central well of 5 mm diameter contained the antigen and was surrounded at a distance of 3.5 mm by six 5 mm wells, equidistant from each other, which contained the test sera. The wells were filled to the brim. After 48 hours' incubation at room temperature precipitin lines were observed, the plates were then washed for seven days with several
Radioimmunoassay for antibody to C. albicans

Changes of ethanol:acetic acid mixture (1:4:5:4:5 v/v) containing 1% glycerol. After decolorisation in the same solvent each specimen was re-examined for precipitin lines.

Results

Radioimmunoassay

As can be seen from Figs 1 and 2, the ranges of antibody levels in the hospitalised group and blood transfusion donors are not comparable. It is evident that the hospitalised group were abnormal with respect to antibody production to C. albicans. The majority of blood transfusion donors had IgG, IgA, and IgM antibody levels of less than 45 μg/ml, whereas many of the hospitalised group had IgG and IgA antibody levels above this value. Thus it appeared that some individuals within this category had been stimulated to produce antibody. The difference in the distribution of IgM antibody levels was not as great, although comparison of Figs 1 and 2 does reveal a slight change of the same type. A few individuals within each group had very high levels of C. albicans antibody.

The finding of a high IgG antibody level (that is, > 45 μg/ml) was not always associated with high IgA or IgM antibody levels. Nevertheless, in 84% of the blood transfusion donors, the IgG, IgA, and IgM antibody levels were at the same point in the distribution (that is, below mean, at mean, or above mean) of each immunoglobulin class. A similar association held for 78% of the hospitalised group. It follows that in the latter group the production of antibody was not confined to particular immunoglobulin classes, in the majority of instances.

Comparison of RIA and Precipitin Test

Figure 3 shows the results of the RIA of IgG antibody and the precipitin test of 74 consecutive sera submitted to the laboratory for routine estimation of C. albicans antibody. In general, it appeared that antibody levels greater than 100 μg/ml were associated with a positive precipitin test, although 11 sera had antibody levels higher than this and were not precipitin positive. The majority of sera with levels within the ranges depicted for the blood transfusion and hospital inpatient groups (< 100 μg/ml) were precipitin negative. Also, it is clear from Fig. 3 that a positive precipitin test can be associated with a wide range of C. albicans levels, with as much as a 14-fold difference between the highest and lowest levels. The results also indicate the improved serological analysis achieved by the RIA and its greater sensitivity compared with the precipitin test.
**Discussion**

*Candida albicans* is found as a normal commensal of the oropharynx and as a pathogen in this site and in the vagina, urinary tract, and skin. In addition, organ and deep tissue infections, although less common, are serious and may lead to septicemia, which is frequently fatal. The difficulty of diagnosis is that isolation of the organism only rarely indicates infection while biopsy to demonstrate tissue invasion can be justified only in certain circumstances. Frequently, therefore, diagnosis has to be by serological means. Agglutination (Preisler et al., 1969), fluorescent antibody (Lehner, 1966), and crossed immunoelectrophoresis (Axelsen et al., 1974; Odds et al., 1975) tests have been used for this purpose, although the most widely used procedures are probably the double gel diffusion precipitin (Ouchterlony) and immunoelectrophoresis tests. The rationale for any of these procedures is that infection in contradistinction to colonisation will stimulate candida antibody production, which can then be detected and, in some instances, quantitated. There is, however, evidence that high levels of antibody frequently exist in healthy individuals. For example, Chew and Theus (1967) found precipitins in the sera of 48% of normals, and Axelsen et al. (1974) in at least 90%. In another investigation, Stallybrass (1964) could not detect precipitins in any normal controls. The situation is therefore confusing. Axelsen (1976), reviewing the problem of serology in candidiasis, concluded that efficient tests should be quantitative rather than qualitative and should be standardised.

Having found a solid phase RIA for quantitation of the antibody in farmer's lung (Parratt et al., 1975) to be preferable to other serological techniques, including a precipitin method, we applied the same principle to the measurement of *C. albicans* antibody. Before any patient-orientated investigations we attempted to establish the range of candida antibody in healthy blood transfusion donors. All of this group had detectable IgG antibody, at levels greater than 5 μg/ml; the majority had IgM levels greater than 5 μg/ml, but half the group demonstrated little or no IgA antibody (< 5 μg/ml). Excluding the latter, the distribution of levels was similar for each immunoglobulin class of antibody, ranging to 45 μg/ml, with only occasional sera beyond this value (Fig. 1). These findings support the view of Axelsen (1976) that candida antibody is present in the serum of all individuals if an appropriate test is used for its detection. Indeed, the variability of antibody levels suggests that different individuals might be responding to different amounts of *C. albicans* (presumably commensal in the gastrointestinal tract and oropharynx) or be responding in
Thus the administration of antibiotics to healthy volunteers has sufficient contact with the drugs to bring about the effects we have described. Certainly the difference between the two groups is important, for it illustrates that a high antibody level may be only a reflection of the change of environment (that of outpatient to inpatient) and cannot be unequivocally regarded as a sign of invasion by *C. albicans*. It is difficult therefore to decide whether to use the distribution for the inpatient or outpatient group as the 'normal range', and we are therefore of the opinion that single estimations of antibody level in any patient are unsatisfactory as the patient's circumstances must be taken into account when trying to assess the significance of the result.

It is clear that the RIA is more sensitive as a serological method than the conventionally used precipitin test (Fig. 3). The group of sera used in this part of the study included patients with heavy colonisation, deep tissue (usually pulmonary) candidiasis, and chronic mucocutaneous candidiasis. Sera with IgG candida antibody levels over 300 µg/ml always gave a positive precipitin test, and, conversely, all sera with levels below 100 µg/ml were precipitin negative. Within the range 100-300 µg/ml some sera were precipitin positive and some negative. The comparison was made between precipitin results and IgG antibody because analogous data of our own (unpublished) and of Hollingdale (1974) have shown IgG to be the important reactant in precipitin tests. From the comparison of the IgG antibody levels and precipitin test it is evident that the patients with moderate levels of antibody gave no consistent precipitin test results, thereby indicating the lack of sensitivity of this technique.

From our own data (unpublished) it is known that many patients with candida infections have IgG antibody levels in the range 100-300 µg/ml, but from Figs 1 and 2 it is evident that 17.5% of the hospitalised adults and 5% of the blood transfusion donors also had antibody levels within this range. Thus it is evident that there is a large overlap in the levels of antibody found in healthy, colonised, and infected adults, and in this situation no single level of antibody can be used as a diagnosis of infection. We believe that the only satisfactory method of assessing the individual's status is to measure antibody levels over a period of time to detect any changes. The RIA is ideally suited to this purpose on account of its reproducibility (± 9% for IgG; ± 12% IgM; ± 16% IgA), which allows accurate definition of the antibody response over short intervals, thereby avoiding delays in diagnosis. In practice, it has been possible to detect increased reactivity to the organism within 48 hours of the onset of heavy colonisation or deep tissue invasion, and studies are in progress to determine whether the
distinction between these two states can be predicted by this kind of careful serological analysis.

In the present work the RIA has provided essential quantitative information on the distribution of antibody in normal and abnormal situations and therefore offers not merely a means of serological diagnosis but a simple technique to study the interplay between host and organism during normal colonisation, over-colonisation, and infection states.

We acknowledge the assistance given by the staff of the Western Infirmary Blood Transfusion Unit and the Regional Blood Transfusion Unit, Law Hospital, in providing sera for this study. In addition, we thank Dr G. Boyd, Respiratory Investigation Unit, Glasgow Royal Infirmary for supplying patients' sera for use as standard and test samples.
