Congenital syphilis in aborted second trimester fetus: diagnosis by histological study

HERBERT BRAUNSTEIN

From the Department of Laboratories, San Bernardino County Medical Center, San Bernardino, California 92404, USA

SUMMARY A case of congenital syphilis in an aborted fetus in the second trimester of pregnancy was documented by demonstration of spirochaetes in the fetal liver, despite the fact that diagnostic studies had not been performed on the mother. Suspection was aroused by the gross and microscopic appearance of the placenta, which appeared identical with that described in proven cases of congenital syphilis. Although these changes have been alleged to be non-specific, the rarity with which such well-developed lesions are encountered in placentas in other circumstances dictates the necessity for further study when they are observed.

Recently we observed an example of congenital syphilis in which abnormalities in the placenta of a macerated fetus, spontaneously aborted in an emergency room in the second trimester of pregnancy, prompted study of the fetus for spirochaetes. The diagnosis of congenital syphilis was established by the demonstration of countless spirochaetes in the autolysed fetal liver.

Case report

A 19-year-old Caucasian woman was admitted to the emergency room with an impending miscarriage. Her past history revealed that the last menstrual period had occurred approximately four and a half months previously with unprotected coitus thereafter. Two days before admission bleeding had occurred, followed the next day by cramping pain. The patient was a transient, allegedly affianced to the father of the fetus, and travelling through the area. A history of promiscuity was not obtained, and the pregnancy was alleged to be her first.

Physical examination revealed a pale young woman with numerous 'condylomata acuminata' and much yellowish vaginal discharge. In the vagina the products of conception could be seen bulging from the dilated cervical os. Haemoglobin was 9·6 g/dl, blood type O, Rh positive, blood sugar 91 mg/dl. No test for syphilis was performed.

A spontaneous, apparently complete abortion occurred. The patient was managed as an outpatient and discharged after about three hours of observation. The fetus measured 128 mm in crown-rump length. The placenta was pale and extremely firm, measuring 7·5 cm in diameter and about 1 cm in thickness. The fetus manifested maceration, and gross interpretation of organ changes was not possible.

Microscopically the placenta was well preserved, with marked enlargement of the placenta villi, which showed both perivascular fibroblastic and endothelial proliferation. The small vessels were quite bloodless. The surface epithelium was a syncytial monolayer (Fig. 1). Rare mononuclear inflammatory cells were noted. Because of the gross and microscopic appearance of the placenta, additional sections were obtained and stained.

Levaditi stain of the placenta did not reveal unequivocal spirochaetes, although two or three suspicious structures were noted. Haematoxylin and eosin stained sections of the fetal liver showed autolytic change and haemopoiesis. Levaditi stains of the liver revealed countless spirochaetes (Fig. 2). X-ray studies and sections of the long bones did not reveal evidence of osteochondritis. Levaditi stains of the lung, heart, and spleen showed occasional spirochaetes in the lung, but none in the heart or spleen.

Discussion

The relative paucity of spirochaetes in the placenta
in congenital syphilis (McCord, 1934) and their abundance in the liver (Von Haam, 1971) have been previously noted. The latter has been attributed to the 'incubator' effect of the uterus in abortion or stillbirth, the spirochaetes multiplying rapidly in the autolysed liver within the retained fetus (Stokes, 1936).

Abnormalities in the placenta in maternal syphilis are uncommon, but they have been described with greater frequency in fetal and neonatal disease (McCord, 1934). McCord listed the features of the syphilitic placenta as diffuse enlargement and crowding of villi; presence of connective tissue in varying density; increase in stromal cells; and lessening or absence of villous blood vessels. In subsequent studies the specificity of these changes has been challenged, and it has been contended that similar alterations may be encountered in the placenta in many other circumstances (Montgomery, 1936; Whipple and Dunham, 1938; Benirschke and Driscoll, 1967).

Russell and Altshuler (1974) more recently described the morphological abnormalities of the placenta at term in three proven cases of congenital syphilis. These included: relative immaturity of villi; focal (largely decidual) plasma cell infiltrations; and vascular obliteration due to endothelial and perivascular fibroblastic proliferation. In one instance, there were granulomas. Neither the first nor the second change appears to be specific for syphilis, and the first would be of major significance only at term. The case here described manifested only the third feature, which appears to be the most specific manifestation of postnatal syphilis as well (Von Haam, 1971).

The frequency with which 'subacute and chronic inflammation' is seen in non-syphilitic placentas, studied histologically, is estimated at 5% by
Benirschke and Driscoll (1967). The same authors state that occasional placentas show obliteratorative vasculitis without syphilis, but they do not illustrate such a lesion. Their photomicrograph of a syphilitic placenta appears identical with ours. While obliteratorative vasculitis has been described in ischaemia, including prolonged placental retention, the characteristic fibromuscular sclerosis of stem arteries is predominantly an endovascular and not a perivascular process (Fox, 1975). Furthermore, in contrast to the predominantly proliferative process of congenital syphilis, with villous enlargement and crowding, retention is characterised by cellular degeneration, atrophy, and disappearance of blood vessels, as well as fibrosis with shrinkage of villi (Benirschke and Driscoll, 1967; Fox, 1975).

At San Bernardino County Medical Center, placentas from more than 50 fetuses of similar gestational age (crown-rump length 120-170 mm) have been examined in the surgical pathology laboratory each year for the last three years. The case described represents the only instance in which the appearance of the placenta prompted an investigation for spirochaetes. Review of the sections of placenta from the 40 most recent similar fetuses personally studied by the author did not reveal any similar histological changes. Minor degrees of oedema and fibrosis of placental villi were observed in a few, but no proliferative vasculitis.

Perhaps the successful documentation of congenital syphilis in this instance was serendipitic, but it appears at least equally probable that the placental changes, if not diagnostic, are characteristic. It is recommended that further studies be initiated whenever similar findings are encountered (Benirschke and Driscoll, 1967).
