Urinary infection with coagulase-negative staphylococci in a teaching hospital

T. L. SHRESTHA AND J. H. DARRELL

From the Department of Bacteriology, Royal Postgraduate Medical School, Hammersmith Hospital, Du Cane Road, London W12, UK

SUMMARY In the eight-month period of study of all urine samples processed in our routine laboratory, only 85 out of 12 152 specimens yielded a bacteriologically significant growth of either Staphylococcus epidermidis or micrococi. Their growth on MacConkey medium was strictly comparable to that on cysteine lactose electrolyte-deficient (CLED) media. Most micrococi isolated were from urine samples of non hospitalised women patients, were resistant to a novobiocin (5 μg) disc, and belonged to Baird Parker type 3. *Staph. epidermidis* came mainly from postoperative surgical inpatients. Their antibiotic sensitivity patterns are variable whereas micrococi are fully sensitive to all urinary antibiotics. We agree that the use of a novobiocin (5 μg) disc for provisional identification of micrococi and *Staph. epidermidis* is simple and practical for a busy routine diagnostic laboratory. The use of more extensive systems to biotype these organisms in a routine laboratory is not practical and not relevant to patient management.

The undoubted role of catalase-positive, coagulase-negative Gram-positive cocci, *Staphylococcus epidermidis*, and *Micrococcus* species in causing urinary tract infection has gradually become accepted in recent years. These organisms did not appear to occur commonly in our routine practice, though other workers have reported an incidence ranging from complete absence (Arneil et al., 1970) to 30% of isolates (Gillespie et al., 1978). We therefore decided to collect and identify all these organisms occurring in urine samples reaching our diagnostic laboratory from inside and outside the hospital in order to establish their frequency and to assess the suitability of our methods for isolation and identification.

Material and methods

Urine samples received in the routine laboratory are cultured without delay or stored for up to 3 hours at 2-4°C on a CHEMLAB Bench Cooler. The well-mixed unspun urine is streaked onto a MacConkey plate (Oxoid CM76) using a calibrated loop delivering 0.003 ml of urine. For the purposes of this investigation duplicate cultures were prepared on plates of Cysteine Lactose Electrolyte Deficient (CLED) Agar, (Oxoid CM301). These were prepared in an exactly comparable manner to the McConkey plates, four specimens being cultured on one plate. A growth of 300 colonies or more of an organism is considered bacteriologically significant. Those yielding 30 colonies or less are discarded.

A wet preparation of the spun deposit (centrifuged for 10 minutes at 2000 rpm) is examined microscopically for formed elements, leucocytes, red blood cells, and bacteria. Those samples which have got pus cells, bacteria, or red cells require primary sensitivity tests, to sulphafurazole (200 μg), trimethoprim (2.5 μg), ampicillin (25 μg), nitrofurantoin (50 μg), and cephaloridine (25 μg). These tests are carried out on lysed blood agar plates ((Iso-Sensitest) Oxoid CM471 with 5% horse blood lysed with saponin) using Stokes’ method and *Escherichia coli* NCTC 10418 as the control organism. After overnight incubation at 37°C all the cultures on CLED medium were read by one of us (TLS), and the results were compared with those of the routine cultures set up at the same time on MacConkey medium. Cultures yielding a bacteriologically significant growth of Gram-positive cocci, as defined above, were tested for coagulase production by the tube method of Gillespie (1943); catalase production was tested by the slide method.

1Present address: Pathology Department, Royal Infirmary, Sunderland.

Received for publication 4 September 1978
in this study. Ten of the 15 micrococi occurred in the group of patients who had never been hospitalised, that is, samples submitted by family practitioners, from the casualty department, and from the antenatal clinic. The other five occurred in hospitalised patients, accounting for only 8% of isolates in this group (Table 2).

All the hospital outpatient isolates were of Staph. epidermidis and occurred in patients who had recently left hospital (Table 2).

All micrococi were found to be sensitive to all antimicrobial agents tested in the primary sensitivity tests. The pattern of sensitivities is different with staphylococci and very variable (Table 2).

### Discussion

The slow recognition of coagulase-negative staphylococci, especially micrococi (Staph. saprophyticus), as urinary pathogens in hospital practice is hardly surprising. In our series, they account for only 7-16% of the significant isolates. We are able to confirm the findings of other workers (Mitchell, 1968; Kerr, 1973; Maskell, 1974; Meers et al., 1975; Sellin et al., 1975; Pead et al., 1977) that they account for a significant proportion of primary urinary infections, Gram-positive cocci occurring in women outside hospital, whereas in a hospital population their contribution is trivial. They do not commonly cause postoperative infections in males; these frequently follow surgery and are caused by Staph. epidermidis. The micrococci isolated by us were all type 3, now reclassified as Staph. saprophyticus biotype 3.

We were able to show that all strains of Staph. epidermidis and micrococi (Staph. saprophyticus) isolated by us from urine samples grew well on our routine MacConkey media. Hence, in our view, there is no need to include a special medium such as CLED when screening urines in order to isolate these organisms, provided the MacConkey medium in use has similar selective properties.

The biochemical methods of Baird-Parker (1963) are relatively time-consuming for the routine laboratory. However, they may be useful in associating

### Table 1 Urine specimens, October 1977-May 1978

| Total number processed in the laboratory | 12 152 |
| Significant bacteriuria due to all kinds of bacteria | 1186 (9.76%) |
| Gram-positive cocci out of all significant bacteriuria | 85 (7.16%) |

*Low total numbers due to failure to perform test.

Reviewing the sensitivity patterns of all our isolates (Table 3), it is surprising that so many strains of both micrococci and Staph. epidermidis are fully sensitive in vitro to sulphonamides and equally surprising that so many of the staphylococci are resistant to trimethoprim. This may reflect heavy usage of cotrimoxazole in hospital patients. In view of the complicated nature of many of the postoperative staphylococcal infections, use of sulphonamides alone would hardly recommend itself as a treatment likely to succeed. The fact that half our strains were resistant to ampicillin is not now surprising, and all strains are, of course, resistant to nalidixic acid. In view of the relative resistance to mecillinam, the place of this antibiotic in treating staphylococcal urinary infections must remain in doubt in spite of the high urinary levels attained. This means that the oral treatment of first choice for such infections would have to be an oral cephalosporin, with nitrofurantoin as a possible alternative.

We thank all the technical staff working in the urine section for their co-operation, Harry Edwards and his staff for preparation of media, and Miss A. Kirk for typing this manuscript.
