A rapid simplified method for plasma 25-hydroxyvitamin D estimation

JUDITH C HAMILTON  South Laboratory and Pathology Block, Southampton General Hospital, Southampton SO9 4XY, UK

Low plasma 25-hydroxyvitamin D (25-OHD) concentrations are common in elderly people, orthopaedic patients, Asian immigrants, and in the later stages of pregnancy.1-3 Though a low plasma 25-OHD concentration is not always associated with osteomalacia, if in old people at least, low 25-OHD levels if left untreated may ultimately lead to metabolic bone disease.4 5 A case might be made for screening for vitamin D deficiency by measuring plasma 25-OHD concentrations. If this were to be practicable, however, the assay technique would need to be simple and rapid. Previously developed competitive protein-binding assays for 25-OHD are tedious, involving long extraction procedures and chromatographic purifications.6 7 This paper describes a simpler technique developed by modifying a method by Belsey et al.8

Material and methods

STEROIDS
Standard 25-hydroxycholecalciferol (25-OHD3) was obtained from the Upjohn Company by courtesy of Dr John Babcock and 25-hydroxy (26(27)-methyl-3H) cholecalciferol (3H25-OHD3), 12-2 Ci/mmol, was purchased from the Radiochemical Centre, Amersham, Bucks, UK.

BUFFER
Barbital acetate buffer was prepared by mixing 0·486 g sodium acetate, 0·787 g barbitone sodium, and 7·65 g sodium chloride in 1 litre of water and adjusting the pH to 8·6 with hydrochloric acid. In order to facilitate solubilisation of steroids, β lipoprotein was added to the buffer. A precipitate of this, obtained by the technique of Besley et al.,9 was washed with ether and then reconstituted to the original volume with barbital acetate buffer. This was added to more buffer at a suitable dilution which maintained non-specific binding at a minimum (1:800).

BINDING PROTEIN
Serum from weanling rats raised on a vitamin D deficient diet for at least three weeks was stored at −20°C. Before use in the assay this was diluted with buffer to a concentration that gave approximately 50% binding of 3H25-OHD3.

DEXTRAN-COATED CHARCOAL
0·5 g dextran (molecular weight 60 000-90 000) and 5·0 g Norit-GSX charcoal were mixed with 200 ml barbital acetate buffer. This was further diluted with buffer (1:10) before use.

SCINTILLATION FLUID
A mixture of toluene and triton X-100 (2:1) was added to 1,4-bis-(5-phenyloxazol-2-yl) benzene and 2,5-diphenyloxazole to give 0·03% and 0·5% solutions respectively.

METHOD
A 200 μl plasma sample was thoroughly mixed with 0·8 ml ethanol and left at 4°C for 30 minutes. On centrifugation 50 μl was transferred to a glass assay tube. Another 50 μl was added to a control tube to monitor non-specific binding. 50 μl aliquots of each of the standards serially diluted in ethanol were transferred to assay tubes. 50 μl 3H25-OHD3 (0·34 pmol), also prepared in ethanol, was added to all tubes, followed by 1 ml barbital acetate buffer, containing 25-OHD binding protein, to the assay tubes and 1 ml buffer alone to the control tubes. After mixing, these were left for 2 hours at 4°C. Unbound steroids were removed using dextran-coated charcoal (500 μl) and, after centrifugation, the supernatants were decanted into vials containing 10 ml of scintillation fluid. The radioactivity was counted in a Packard β-counter. Percentage binding of 3H25-OHD3 was calculated from—

Counts from assay tube—counts from control tube.

Total counts added

From this a standard curve was obtained by plotting the percentage of bound 3H25-OHD3 against log mass of 25-OHD3 (Fig. 1). 25-OHD concentrations (nmol/l) in individual plasma samples could then be obtained by reference to the standard curve (2·5 nmol/l is equivalent to 1 ng/ml).

Results

STANDARD CURVE
The standard curve obtained is shown in Fig. 1 and covers the workable range. The sensitivity of the assay system is 5 nmol/l, as defined by Ekins.10

PRECISION
The intra-assay coefficients of variation for 10 samples containing 30 nmol/l and 10 samples...
Technical methods

Plasma 25-OHD concentrations in 47 healthy adults aged 19 to 41 years showed a logarithmic distribution giving a geometric mean of 65 nmol/l, with 95% confidence limits of 20 to 215 nmol/l. A histogram of the distribution of the values is markedly skewed, most values lying below 100 nmol/l (Fig. 2).

Discussion

The results confirm a competitive protein-binding assay, without preparative chromatography, that gives valid plasma 25-OHD estimations. The method has limitations of specificity in that, although it measures all 25-OHD₃ and 25-OHD₂, it includes variable amounts of 24,25-(OH)₂D₃, thus elevating values slightly. Some subjects, therefore, with actual low concentrations of 25-OHD would present within the reference range while those subjects with real normal levels would continue to exist within this range. In effect, when screening for vitamin D deficiency using this method, some false-negative results may be obtained but no false positives. A more specific test may be indicated in subjects with levels bordering on the lower limit of the reference range.

The assay has the advantage of high precision and speed of performance. The extraction of 200 µl of plasma by a small volume of ethanol allows consistent recoveries of over 95% and removes the need for internal monitoring. Ethanol extracts may, therefore, be used directly in the assay system without reduction under nitrogen.

**Accuracy**

Recovery of [³H]25-OHD₃ added to five plasma samples was 97 ± 3%. A linear regression calculated for estimated 25-OHD against added 25-OHD₃ gave a correlation coefficient of 0.98.

**Specificity**

Cross-reactivity with different steroids at 50% displacement from zero binding is shown in the Table. Only 25-hydroxyergocalciferol (25-OHD₂) and 24,25-dihydroxycholecalciferol (24,25-(OH)₂D₃) caused significant interference.

**Reference Range**

Plasma 25-OHD concentrations in 47 healthy adults aged 19 to 41 years showed a logarithmic distribution giving a geometric mean of 65 nmol/l, with 95% confidence limits of 20 to 215 nmol/l. A histogram of the distribution of the values is markedly skewed, most values lying below 100 nmol/l (Fig. 2).
Technical methods

The concentrations of 25-OHD in young adults estimated by the technique are comparable with those found by workers using other methods where mean values are 68 nmol/l, 77 nmol/l, and 98 nmol/l. Studies utilising the technique have included a review of 62 patients admitted to a geriatric unit, assessments of the responses of old people to vitamin supplements and to ultraviolet light, and a large-scale review of 298 old people living at home. The successful completion of such studies gives further support to the view that the technique described in this paper would be of practical value as a method of screening for vitamin D deficiency.

Letters to the Editor

Failure to demonstrate specificity of the morphological and histochemical changes in mucosa adjacent to colonic carcinoma (transitional mucosa)

We have recently come across a case of primary adenocarcinoma of the caecum invading the appendix, which seems to support the suggestion made by Isaacs et al. that the morphological mucosal hyperplastic changes seen adjacent to large bowel carcinomas are probably a secondary effect of the tumour presence.

The patient was a 64-year-old woman who presented with a three-year history of abdominal pain and a recent onset of diarrhoea and general weakness. A mass was found in the right iliac fossa and a malignant tumour was diagnosed, for which a right hemicolectomy was performed.

The caecum contained a nodular, ulcerated tumour mass that involved the whole circumference of the caecum and extended vertically for up to 6 cm. The tumour was infiltrating the whole thickness of the bowel wall, the ileocaecal region, the base of the appendix, and several mesenteric lymph nodes.

Histologically, the tumour was an adenocarcinoma showing variable degrees of differentiation, some areas being moderately or poorly differentiated and others showing a predominance of 'signet-ring' malignant cells. Stains for argentaffin granules were negative.

Sections of the base of the appendix (Figure) showed tumour tissue, at one side, in lymphatics and invading the wall and adjacent fibrofatty tissue to a variable extent. The appendiceal mucosal epithe-
