A mechanised batch screening method for the detection of bacteriuria

P KERFOOT, D McGHIE, E CAHILL, T FOUNTAIN*  
Department of Clinical Microbiology, Bury General Hospital, Bury, Lancashire

In the modern hospital microbiology department, it is not feasible to investigate fully all routine urine specimens for the detection of bacterial infection of the urinary tract. Although increased numbers of leucocytes in the urine may enable selection of urines for comprehensive culture techniques, including direct antibiotic sensitivity testing, it is totally unacceptable to reject any specimen with a normal leucocyte count without performing a screening culture.

An advance in efficient screening, using blotting paper strips, was described by Leigh and Williams and is now successfully used in many hospital laboratories.

The method now described however, involves the mechanical inoculation of 25 urine specimens simultaneously onto an agar surface in a way which reduces both time and materials to a minimum.

Materials and methods

The urine specimens studied were preserved immediately using boric acid in a 5 ml screw cap container, designed initially for paediatric use and now produced commercially (Sterilin Ltd, Middlesex, England).

Twenty-five uncapped urine specimens were placed in a 100 mm square dish divided into compartments. The plate acts as a holder which fits on the carriage of a modified multipoint inoculator (Denley, Sussex, England). The inoculator modification was firstly to increase upward lift of the rods and secondly to give a suitable spacing to the 5 x 5 configuration. The 25 precision ground steel rods inoculate 1 μl of each specimen onto the agar surface of a 100 mm square dish containing 30 ml CLED agar (Oxoid).

Quantitative surface viable counts were performed on urines by spreading 10 μl of a 1/10 dilution in Ringer's solution over the surface of a CLED agar plate.

Results

The Figure shows the resulting graph comparing the number of colony-forming units (CFU) determined by both methods on urines showing discrete countable colonies on the multipoint inoculum.

The calculated line of regression is virtually identical for both Gram-positive and Gram-negative organisms with 10 CFU on the multipoint inoculum being equivalent to a count in the region of 10^7 CFU/l of urine.

Discussion

The blotting paper strip method works well for screening urines containing 10^8 organisms/l but is less reliable below this level. It is now recognised that counts of 10^7 organisms/l of a pure growth are often of significance in both antenatal and other patients. The mechanical method allows assessment of purity of growth between 10^7 and 5 x 10^8 organisms/l and often above this level. The urines not rejected on the basis of the screening test should be fully cultured from the original stored urine as, in common with the paper strip method, confusion and delay may occur by working from the colonies of the screening culture.

The handling of urines in batches of 25 is compatible with the convenient and efficient batch method for performing urine microscopy, which utilises microtitre plates with flat bottomed wells viewed through an inverted microscope.
During the course of one year, the use of the small containers has been accepted by the nursing staff without any problems being encountered. Improved handling of urine specimens has been achieved; the mechanical method demonstrating itself as an efficient labour saving and highly cost effective procedure in the laboratory.

Bone histomorphometric analysis in familial hypocalciuric hypercalcaemia

According to recent publications, familial hypocalciuric hypercalcaemia is a relatively common disease but with as yet unknown physiopathology. We report here histomorphometric analysis of the bone of a mother and son showing clinical and biological symptoms of the condition: hypercalcaemia without other features of familial multiple endocrine neoplasia type 1, hypermagnesaemia, hypocalciuria, normal concentration of parathormone (PTH), and abnormal serum calcium concentrations after parathyroidectomy.

Transiliac bone biopsies were performed after double labelling with tetracycline. The following histomorphometric parameters were measured: trabecular bone volume, relative trabecular resorption surface, relative trabecular osteoid volume and surfaces, thickness index of osteoid seams, and mineralisation rate. Histomorphometric results were compared to Meunier’s normal values. They are shown in the following Table.

Table Bone histomorphometry in a mother and son with familial hypocalciuric hypercalcaemia
