Clear cell carcinoma of the lung

C EDWARDS, A CARLILE
From the Department of Histopathology, East Birmingham Hospital, Birmingham

SUMMARY Six tumours of the lung initially classified as clear cell carcinoma, were studied. Examination of further material by light and electron microscopy showed adenocarcinomatous differentiation in three cases and squamous differentiation in two. One case showed the features of a large cell anaplastic carcinoma. The clear appearance of the cytoplasm in paraffin sections was due to accumulations of glycogen that were partially removed during processing. It is concluded that clear cell carcinoma is not a single and separate entity.

Clear cell carcinoma of the lung is defined by the World Health Organisation as an anaplastic large tumour forming nests, clusters, and sheets of cells with large vesicular nuclei and an abundant clear or foamy cytoplasm, which may or may not contain glycogen. No mucin is present, and this category does not include adenocarcinomas or squamous carcinoma with clear cells. The resemblance of such tumours to carcinoma of the kidney may give rise to diagnostic problems. Few studies of this variant of lung cancer have been reported, and only two were originally written in English. As far as we are aware, the ultrastructure has been described in only one case. As widespread clear cell change can occur in squamous carcinoma and adenocarcinoma of the lung, the existence of clear cell carcinoma as a separate entity has been questioned. We investigated the light and electron microscopic features in six cases coming to surgery at this hospital. Our results indicate that clear cell carcinoma is a heterogeneous group of neoplasms, with only cytoplasmic accumulation of glycogen in common.

Patients, material, and methods

All the patients were heavy cigarette smokers. One patient (case 5) was thought at first to have a renal carcinoma with a secondary deposit in the lung, but intravenous pyelography, renal arteriography, and surgical exploration of the right kidney did not show any abnormality. Three patients (cases 1, 2, and 6) were treated by lobectomy, two (cases 3 and 4) by pneumonectomy, and one (case 5) by right upper and middle lobectomy. One patient (case 6) presented five months after operation with chest pain, dyspnoea, and haemoptysis. Radiologically, there was a cavitated tumour in the right upper lobe, and an inoperable tumour extending into the pleura was found at thoracotomy. She died two months later. The other patients did not suffer a recurrence, but the maximum follow up period was only 14 months. The table shows the clinical details of all six patients studied.

LIGHT MICROSCOPY
In each case the initial diagnosis of clear cell carcinoma was made on three paraffin sections stained with haematoxylin and eosin, periodic acid Schiff with and without diastase, and mucicarmine. These sections were reviewed, together with a bronchial biopsy from case 4, and an open biopsy taken during the second operation from case 6. Subsequently, up to six extra blocks were obtained from each resected specimen, and the sections were stained again with haematoxylin and eosin, periodic acid Schiff, and mucicarmine.

ELECTRON MICROSCOPY
With the exception of case 5, tissue for electron microscopy was obtained at the time of thoracotomy and fixed in buffered glutaraldehyde. In case 5 material was obtained from the specimen fixed with formalin. In all cases the tissue was fixed afterwards in osmic acid and embedded in resin tagged with typhoid-paratyphoid A and B vaccine (TAAB Laboratories Ltd, Reading, England). Ultra thin sections were stained with uranyl acetate and lead citrate. Between six and 10 blocks were examined in each case.

Results

LIGHT MICROSCOPY

In cases 1, 2, 3, and 5 the tumour consisted of sheets and clusters of polygonal cells up to 40 μm in maximum diameter (Fig. 1). Cell borders were distinct, and the cytoplasm was water clear or foamy and faintly eosinophilic. Nuclei were 10–20 μm across and round or slightly irregular with an open chromatin pattern and often a single large eosinophilic nucleolus. There were moderate numbers of mitoses. In many fields the stroma was scanty and infiltrated by plasma cells and lymphocytes. Elsewhere it was more prominent, and some areas were scirrhouous, with small aggregates of cells surrounded by cellular fibrous tissue.

In cases 4 and 6 tumour cells were arranged in broad irregular trabeculae, with pseudoacinar spaces containing cellular debris (Fig. 3). The pattern resembled that of well differentiated squamous carcinoma, but there was no stratification or keratinisation and no intracellular bridges. The cells were smaller than those in the first group, measuring up to 15 μm in maximum diameter. Nuclei were oval, round, or irregular and up to 9 μm across with two or three small nucleoli. Mitoses were less common. Diastase labile material positive for periodic acid Schiff was present in the cytoplasm. Stains for mucin in the original sections were negative, but in the additional material from cases 2 and 3 occasional foci of extra and intracellular mucus secretion were seen.

Necrosis was variable and most pronounced in case 1. In case 3 the periphery of the tumour showed a lepidic type of spread with preservation of alveolar walls. Hilar nodes were affected in case 2. Abundant intracytoplasmic material, positive for periodic acid Schiff, removable by diastase, was present (Fig. 2). Stains for mucin in the original sections were negative, but in the additional material from cases 2 and 3 occasional foci of extra and intracellular mucus secretion were seen.

The bronchial biopsy from case 4 consisted of...
normal bronchial mucosa. A specimen taken at the second operation from case 6 showed poorly differentiated squamous carcinoma without clear cell change.

**ELECTRON MICROSCOPY**

In all the cases most tumour cells contained glycogen granules, either in compact masses or dispersed throughout the cytoplasm (Figs. 4–7). The larger masses were sharply defined, but no limiting membrane was present. In cases 2, 3, and 5 foci of adenocarcinomatous differentiation were present, with intercellular lumens lined by microvilli and bounded by tight junctions or complete junctional complexes (Fig. 4). Some cells contained numerous mucus granules (Fig. 5), whereas in others they were sparse or absent. Mitochondria were plentiful. Cisterns of smooth endoplasmic reticulum were often abundant and were sometimes dilated to form large vacuoles, which were either empty or contained a few granules of glycogen (Fig. 4). Nuclei were
irregular with prominent nucleoli. There were also areas of undifferentiated, polygonal cells with smooth cytoplasmic membranes bearing occasional tight or gap junctions (Fig. 6). Organelles were sparse, and nuclei were oval or irregular, with prominent nucleoli. The tumour from case 1 consisted entirely of this type of cell.

In cases 4 and 6 the light microscopic impression of squamous carcinoma was confirmed (Fig. 7). Projecting cell processes were joined by well developed
desmosomes, and tonofilament bundles were present in the cytoplasm (Fig. 7). No granules of keratohyaline were seen, and other organelles were scanty. Nuclei were round or slightly irregular and contained one or more nucleoli.

Discussion

In 1955 Walter and Pryce first drew attention to carcinomas of the lung composed predominantly or entirely of clear cells, but it was not until nine years later that Morgan and Mackenzie published a study dealing specifically with clear cell carcinoma. They described 13 cases, emphasising the peripheral origin and the resemblance to secondary renal carcinoma. Between 1966 and 1981, 27 further examples were reported, and in 1984 Smirnova et al reported the ultrastructure of one case.

In 1980 the existence of this tumour as a distinct subtype was questioned by Katzenstein et al, who reviewed 348 consecutive cases of pulmonary carcinoma and found 15 that contained over 50% clear cells. These tumours, which were otherwise large cell undifferentiated, epidermoid, or adenocarcinomas, would have been considered to be clear cell carcinomas according to the criteria published up to that date. As the authors pointed out, however, these criteria were imprecise. The number of clear cells required before clear cell carcinoma could be diagnosed had not been specified, nor was there any mention of tumours showing glandular or squamous differentiation. It was concluded that clear cell change is common in all types of carcinoma of the lung except small cell carcinoma, and that even those tumours consisting predominantly of clear cells should be classified under one of the major categories, laid down by the World Health Organisation (adenocarcinoma, squamous carcinoma, or large cell carcinoma), at the same time noting the clear cell component.

Wagner's group reached similar conclusions, and, interestingly, clear cell change has been reported in carcinomas arising from Clara cells and in large cell undifferentiated carcinomas. Moreover, by modern criteria many of the earlier reported cases are not true clear cell carcinomas. For instance, intracytoplasmic mucin was found in all the tumours collected by Morgan and Mackenzie, and over half showed acinar differentiation. Such tumours would now be classified as adenocarcinomas with clear cell change, as would the tumours reported by Drut et al.

This study confirms that clear cell carcinoma is not a separate entity. Examination of further material by light microscopy alone showed mucus secretion in two cases and squamous differentiation in one. Although three cases fulfilled the current light microscopic criteria for clear cell carcinoma, at an ultrastructural level one was an adenocarcinoma, one a squamous carcinoma, and one a large cell undifferentiated carcinoma. The clear appearance of the tumour cells is due to accumulations of glycogen, most of which is dissolved during the preparation of paraffin sections: in tissue processed for electron microscopy it is retained. This change seems unlikely to be degenerative as it is not necessarily associated with necrosis and is also seen in secondary deposits, but it may reflect an abnormality in glycolysis.

Primary carcinomas of the lung with clear cell change, secondary renal adenocarcinomas, and clear cell adenoma of lung (sugar tumour) show similar histological structure, and all contain cytoplasmic glycogen. The distinction between these tumours, which is obviously important in relation to their management and prognosis, may be impossible in small biopsies. Where the availability of tissue permits, multiple sections should be examined for evidence of mucus secretion and squamous differentiation. Renal adenocarcinomas contain neutral lipid and phospholipid, and mucopolysaccharides are not found in the cytoplasm, although they may be found in cell membranes. Electron microscopy shows prominent microvilli, pinocytic vesicles, vacuoles containing lipid, and often elongated and tortuous mitochondria. Clear cell adenoma shows little nuclear pleomorphism, mitoses are scanty or absent, and the cells are arranged around thin walled branching vascular channels.

In contrast to other clear cell tumours, the glycogen is usually contained in membrane bound vesicles, but in one reported case it was dispersed throughout the cytoplasm.

We thank Dr Pandov for translating the Russian articles cited in this paper and Mrs Ruth Fry for secretarial help. This study was supported by a grant from the West Midlands Regional Health Authority.
