Cerebral and orbital *Aspergillus* infection due to invasive aspergillosis of ethmoid sinus

SUMMARY  *Aspergillus fumigatus* infection due to primary infection of the ethmoid sinus affected the brain and orbit of an otherwise healthy elderly woman. Primary nasal sinus infection may be a chronic process analogous to aspergilloma of the lung: it may, however, assume a locally invasive course and spread to the orbit or brain, as in the case described. This form of *Aspergillus* infection is rare in Europe but common in hot dry areas like the Sudan. The infection was probably contracted by our patient while on holiday in South Africa.

Histological recognition of the condition is important in these unusual sites—many cases are clinically diagnosed as a tumour and undergo biopsy.

Case report

A 74 year old woman collapsed while out shopping. On recovery she gave a history of intermittent frontal headaches, which she had had for one year since returning from a holiday to South Africa. Examination showed a right ptosis and proptosis, but full neurological examination was otherwise normal. She was admitted to hospital where she was noted to be intermittently confused and incontinent of urine.

Cranial radiographs and ultrasonographic examination of her right orbit yielded normal results. Computed tomography showed a large multilobular mass affecting the frontal poles, with peripheral enhancement and severe surrounding oedema (Fig. 1). There was also a low density mass obscuring the right ethmoid sinus, extending into the right orbit. This lesion was considered to be a primary cerebral tumour; surgery was not indicated. Her condition deteriorated, and she suffered increasing periods of confusion and drowsiness before her death.

Post mortem examination showed that the tumour was an abscess filled with cream coloured purulent material. It occupied the right frontal pole medially and extended into the left frontal lobe. The abscess was 4-5 cm in diameter and had irregular margins (Fig. 2). The inferior part of the cavity adhered to the orbital plate and surrounded the optic nerve close to its entry into the orbit. The bone was macroscopically intact. Examination of the right orbit showed the posterior structures to be obscured by firm white tissue with no spread to the globe. Similar firm white tissue without macroscopic necrosis obscured the ethmoid sinus on the right. The other nasal sinuses

Invasive aspergillosis of ethmoid sinus

Invasive aspergillosis with old organising thrombus in arteries is a systemic infection contained within tissues and may have predisposed the patient to an immune deficient state.

Culture of material from the cerebral abscess wall showed a pure growth of Aspergillus fumigatus.

Discussion

Spread to the nasal sinus by Aspergillus may take three forms, which parallel those seen in the lower respiratory tract; saprophytic infection (mycetoma), allergic aspergillosis, and invasive aspergillosis.

Saprophytic infection is a chronic indolent form of the disease localised to the nasal sinus. This is the most common form of sinus disease and is endemic in the Sudan.2 3 There are thought to be three predisposing factors to this high incidence in the Sudan: the dry climate, a high content of Aspergillus spores in the soil, and a high atmospheric dust content. Clinically, symptoms include headache, rhinorrhea, and post-nasal discharge.

Allergic Aspergillus sinusitis is a recently described condition in which the affected sinuses are filled with mucoid material containing numerous eosinophil leucocytes, cellular debris, and Charcot-Leyden crystals. Scattered fungal hyphae are present.4

Invasive Aspergillus infection occurs when there is spread to the sinus wall and extension into the surrounding tissues. The reason for a saprophytic infection becoming invasive is not known. Invasive infection stemming from a pulmonary primary site is often seen in patients who are immunosuppressed. Notably, most of the published cases of primary rhinocerebral Aspergillus infection are not recorded as having a condition liable to cause an immunosuppressed state. The most common pathogenic organism in reported series of primary rhinocerebral aspergillosis has been Aspergillus flavus, but these cases are mostly from the Sudan and may reflect a local pattern of disease. Cases from outside the Sudan have shown other species including Aspergillus fumigatus.2 4 7 8

Our patient probably developed a saprophytic sinus infection while she was on holiday in South Africa, producing a localised disease which resulted in the symptom of headache for one year. Invasive infection then developed with local extension into the orbit and brain.

In a review of thirty cases of orbital aspergillosis (the bulk of published cases) 21 had proptosis, 24 had nasal sinus disease, and six had cerebral disease.4 Initial diagnosis was made mainly after histological examination of biopsy material.

The main histological diagnostic feature of rhinocerebral aspergillosis is the presence of a histiocytes or giant cell reaction to fungal hyphae. The diagnosis of a fungal infection in this site should be considered whenever a biopsy, usually performed to make a

diagnosis of a tumour, contains necrotic tissue with occasional histiocytic giant cells. The identification of fungal hyphae in this type of necrotic tissue may be difficult due to degeneration and ballooning of the hyphae. The two main primary fungal infections affecting the region of the nasal sinuses and brain are Aspergillus and Zygomycosis (formerly phycomycosis). Histological sections show that the Aspergillus hyphae are thin (3–6 μm), have regular parallel walls with easily seen septa, and show a regular dichotomous branching pattern at acute 45° angles. In contrast, the hyphae in a zygomycotic infection are broad (6–25 μm), have irregular contours to the hyphal walls, and have an irregular branching pattern with only very occasional septa. It is usually impossible, however, to identify a fungus in a small biopsy with a few degenerate hyphae without resorting to culture. Degenerate Aspergillus hyphae will lose septa and become swollen so that they resemble a zygomycosis. Care should therefore be exercised in the interpretation of biopsy material.5 6

A complication of cerebral invasion by aspergillosis is mycotic arteritis. This is due to direct invasion of small vessel walls by the fungal hyphae. In one reported case this led to fatal intracranial haemorrhage.7

Treatment of invasive rhinocerebral aspergillosis by antifungal chemotherapy has been regarded as being generally ineffective. Surgical excision is recommended as the most effective means of controlling the disease.4 8

In conclusion, we have described a case of Aspergillus infection with a pattern, which, while well recognised, is very unusual in Europe. With the increase in travel to climates in which this pattern of disease is common, awareness of this type of presentation and biopsy diagnosis warrant wider consideration.

The culture of the Aspergillus was performed in the department of microbiology, Queens Medical Centre, Nottingham, by Janet Crowley. We are grateful to the Mycological Reference Laboratory, Colindale, for confirmation of the fungal type. We thank Dr PJ Toghill for permission to report this case. The photomicrographs were produced by Mr Bill Brackenbury of the department of histopathology.
