Histopathogenesis of intestinal metaplasia: minute lesions of intestinal metaplasia in ulcerated stomachs

K MUKAWA, T NAKAMURA, G NAKANO, Y NAGAMACHI

SUMMARY Minute lesions of intestinal metaplasia composed of a few metaplastic tubules were observed in the gastric mucosa during routine histological examination of gastrectomy specimens. The histological findings indicated that these lesions might be an initial stage of more advanced intestinal metaplasia. Accordingly, more than 18,000 serial sections in 10 stomachs with chronic ulcers were examined to clarify the histopathogenesis of the intestinal metaplasia. It was concluded from the three dimensional reconstruction of minute intestinal metaplasia lesions that these lesions originated during the regenerative process of healing of gastric erosions. The lesions were roughly globoid with a depression on the surface. It is thought that with continuous formation and healing of gastric erosions, more extensive intestinal metaplasia lesions would be formed by an increase in size and confluence of these focal minute intestinal metaplasia lesions.

Although theories regarding the histogenesis of intestinal metaplasia have been published by many investigators, controversy still exists. Moszkowicz mentioned that intestinal metaplasia originated from undifferentiated regenerative epithelium in the initial stages of ulcer healing. Oohara also recently reported that intestinal metaplasia commonly occurred as a regenerative process in ulcers. On the other hand, Murakami and Oohara proposed that intestinal metaplasia occurred through the transformation of proliferative cells in the necks of gastric tubules. Moreover, Hattori studied small carcinomas and concluded that intestinal metaplasia, dysplasia, and adenocarcinoma can arise coincidentally in the proliferative cell zone in the neck region. We, however, have rarely seen the initial stage of a minute intestinal metaplasia lesion confined to the neck region of the tubules. Minute intestinal metaplasia lesions measuring less than 1.5 mm in diameter, which were regarded as an initial stage of intestinal metaplasia, showed a depression on the surface. In the adjacent mucosa clusters of regenerative epithelial cells were observed and the muscularis mucosae was split or thickened by fibrosis, or both. There was an infiltrate of lymphocytes around the lesions. These histological findings indicate that focal intestinal metaplasia is derived from the repair process of gastric erosions. From these findings it was concluded that more extensive intestinal metaplasia lesions would be formed by an increase and confluence of these focal minute intestinal metaplasia lesions. Accordingly, we decided to observe smaller intestinal metaplasia lesions in greater detail to elucidate their histogenesis, by examining the three dimensional structure of the lesions and the adjacent mucosa, using histological sections.

Material and methods

Ten stomachs in which there was mild intestinal metaplasia were selected from 66 stomachs from patients with peptic ulcers which had been resected between 1979 and 1985 at this hospital. Of these 10 stomachs, four had been resected for stomach ulcer, four for duodenal ulcer, and two for gastroduodenal ulcer. The stomachs were fixed in 10% formalin. The gastric mucosa, including the ulcers, was cut into 5 mm thick rectangular blocks and all of these were processed and embedded in paraffin wax. Five micrometer sections were cut and stained with haematoxylin and eosin and were examined for minute intestinal metaplasia lesions. More than 18,000 serial sections were made from the 35 blocks in which minute intestinal metaplasia lesions were found, to study their three dimensional structure. In this way we were able to define

Accepted for publication 21 July 1986
their form, that of the neighbouring mucosa, and to measure them three dimensionally. In defining the characteristic feature of minute intestinal metaplasia lesions as “minute” we included only those lesions measuring less than 1.5 mm.

**Results**

In the 10 stomachs studied we found and reconstructed 52 minute intestinal metaplasia lesions three dimensionally from more than 18 000 serial sections. Fig 1 shows a typical example of these lesions arising in the intermediate zone of the mucosa. These foci were seen randomly in the stomachs and had no specific distribution. The average age of all subjects was 45.6 years.

Fig 2a shows how metaplastic tubules began to appear in the left sections (1–4), increased in number of the upper and middle sections (5–8), and gradually disappeared in the lower sections (9–12). Microscopic three dimensional morphology showed that this lesion was roughly globose with a dimple on the surface and was 0.55 mm wide and 0.75 mm thick. Fig 2b shows an enlargement of part of fig 2a (black rectangle). A noticeable decrease in the pyloric gland was observed at the centre of the minute intestinal metaplasia lesion. The neighbouring mucosa showed no intestinal metaplasia at all, and was composed of hyperplastic foveolar epithelium. The muscularis mucosae was split and thickened by fibrosis at the base. Hyperplasia of lymphoid tissue was seen in the adjacent mucosa. The metaplasia was of the complete type and included Paneth cells. Fig 3a is a complete serial section of another, smaller lesion which was composed of a few metaplastic tubules and measured 0.52 mm wide and 0.66 mm thick. Fig 3b shows an enlargement of the photomicrograph within the black frame rectangle. The clusters of regenerative foveolar epithelial cells were clearly seen on both sides with a considerable decrease in size of the pyloric glands at the centre of the lesion. Hyperplasia of lymphoid tissue and splitting and fibrous thickening of the muscularis mucosae was also observed. A minute intestinal metaplasia lesion was seen adjacent to the erosion in the process of repair. The opening of the tubules showed nests of epithelial cells, which showed transition from regenerative undifferentiated epithelium to intestinal epithelium. The intestinal metaplasia was the complete type, including Paneth cells.

Fig 4 also shows a minute intestinal metaplasia lesion with typical foci of regenerative undiffer-

Entiated epithelium. There was a nest of metaplastic tubules that suggested transition from the regenerative undifferentiated epithelium to intestinal epithelium towards the base of the lamina propria. The term “regenerative undifferentiated epithelium” is used in this study to mean hyperplastic epithelium with a syncytium like appearance, which is not yet differentiated to gastric epithelium or intestinal epithelium. The epithelial cells were “flattened” or cuboidal, had partial or complete loss of the normal mucin content, and had decreased amounts of cytoplasm with an increase of basophilia. Their limiting

Membranes were indistinct. This regenerative undifferentiated epithelium was found in 41 of 52 (78.8%) minute intestinal metaplasia lesions from the serial sections examined.

Discussion

Although a large number of epidemiological,6 histopathological,1–5 and experimental8 studies on the intestinal metaplasia of the stomach have been carried out, a three dimensional histopathological study of minute intestinal metaplasia lesions in the stomach has not as far as we know been reported.

The present study shows that 52 minute intestinal metaplasia lesions that had to have arisen from the regenerative process of healing of gastric erosions (fig 5) exhibited the following characteristics: a rough globoid appearance with a depression on the surface

three dimensionally; an appreciable reduction in size in the pyloric glands at the centre of the lesions; splitting or fibrous thickening of the muscularis mucosae at the base of the lesion; hyperplasia of the lymphoid tissue between the lesion and adjacent mucosa and in some cases clusters of regenerative foveolar epithelial cells in neighbouring mucosa. It was therefore concluded that these minute intestinal metaplasia lesions originated during the repair process of erosions.

In previous studies on the histogenesis of intestinal metaplasia Moszkowicz suggested that it was the result of incomplete regeneration of surface epithelium which has been repeatedly damaged, and that regenerative undifferentiated epithelium in each healing erosion has the potential to change its differentiation from a gastric to an intestinal pattern.1 In later studies some authors thought that intestinal metaplasia might be a reactive change due to tissue

injury in the course of a disease.9 Oohara reported an experimental study in which intestinal metaplasia of the regenerative epithelium was successfully induced in rats simply by treating the gastric mucosa with 0.5N sodium hydroxide, and from the histological study of the regenerative epithelial of 549 foci of gastric ulcer it was concluded that regenerative epithelium often gives rise to intestinal metaplasia during the regenerative process.2

From this histogenetical study of a minute intestinal metaplasia lesion, it seemed that the lining epithelium in the healing erosion initially takes the form of regenerative undifferentiated epithelium as an expression of regeneration and is then transformed into intestinal epithelium or pseudopyloric gland (fig 6). We could detect minute intestinal metaplasia lesions in which healing erosions and transitions from regenerative undifferentiated epithelium to intestinal epithelium coexisted (fig 5). This finding also supports the above mentioned theory of the histogenesis of intestinal metaplasia.

Okuda reported that multiple minute erosions were often observed endoscopically in the antral mucosa, that metaplastic tubules were discovered only in the depressed mucosa in the early stages, and that in time, these metaplastic foci extended and merged with each other, supporting Moszkowicz’s theory.10

We concluded from the three dimensional reconstruction that most of the minute intestinal metaplasia lesions arising in the regenerative process of erosion healing and more advanced intestinal metaplasia lesions would be formed by an increase and confluence of such lesions, which arose from repeated erosions and repairing by intestinal metaplasia (although we cannot refute the mutation theory proposed by Oota,4 Murakami,3 and Hatton5). We are indebted to Dr JR Jass for his kind assistance in the preparation of this manuscript. This study was supported by grants-in-aid for cancer research from the Ministry of Health and Welfare (60–35) and the Ministry of Education, Science and Culture of Japan (59010091).
