Abstract

The feasibility was studied of in situ hybridisation using chromosome specific DNA probes on paraffin wax embedded normal and malignant tissues from different organs. Both isolated nuclei and 5 μm sections were used in in situ hybridisation experiments with biotinylated repetitive DNA probes specific for the centromeric regions of chromosomes 1 and 17. The hybridisation results were visualised with peroxidase-diaminobenzidine. The optimal pretreatments with sodium thiocyanate and pepsin were experimentally defined for the different tissues.

Although interphase cytogenetics on paraffin wax embedded tissue is possible, the results indicate that it has its limitations, compared with investigations on fresh tumour tissue.

Tumour cells often show numerical or structural chromosomal abnormalities. These aberrations may, in some cases, provide clues to the initial changes which caused the tumour to arise. Such aberrations may also correlate with the behaviour of the tumour and have prognostic value, in which case the findings could be used to determine clinical management. A great deal of effort has therefore been invested in the cytogenetic analysis of malignancies. The classic technique of karyotyping Giemsa banded metaphase chromosomes is still mostly used to generate detailed information on the chromosomal content of neoplastic cells. For solid tumours, however, several disadvantages are inherent in this approach.

First, tumour tissue often has to be cultured to obtain sufficient metaphases. A relatively low success rate of only 60% in obtaining good metaphases is reported.2 When successful, the number of metaphase spreads is often small, and because of culture effects it is questionable whether these are representative of the original tumour cell population. As a consequence knowledge of cytogenetic aberrations in solid tumours is poor when compared with that in haematological malignancies.

An alternative method for the study of chromosomal abnormalities is the measurement of abnormal DNA content of cell nuclei using flow cytometry. This technique is extremely rapid and results are representative of the cells in the sample. In 1983 Hedley described the use of nuclei isolated from formalin fixed, paraffin wax embedded tissue in DNA flow cytometry.3 Because of the relative simplicity of the technique, many investigators have attempted to use tumour material from the (large) paraffin wax archives to correlate abnormal DNA content with prognosis for a large variety of tumours. In his review article published in 1989 Hedley mentions more than 100 of these studies.4 A major drawback, however, is the "limited cytogenetic sensitivity": a "small" change in nuclear DNA content like the loss of one complete chromosome often remains undetected.5 Furthermore, when abnormal DNA content is found, the question remains as to what cytogenetic changes have occurred.

A third technique for the study of cytogenetic changes in solid tumours is in situ hybridisation using chromosome specific DNA probes. DNA sequences can be detected in interphase nuclei ("interphase cytogenetics")6 as well as in metaphase spreads, thereby obviating the need to culture tumour material. A limitation of interphase cytogenetics is that it only generates information for those chromosome regions to which the probes can hybridise. Application of interphase cytogenetics has been described for solid tumours of bladder,7,8 breast,9 stomach,10 and brain.11 In all these studies nuclei isolated from fresh tumour material were examined. Studies on paraffin wax embedded tissues have so far been restricted to tissue sections of bladder carcinomas12 and testicular tumours.13,14 A disadvantage of the use of 5 or 10 μm thick tissue sections is that the number of hybridisation signals per nucleus will be an underestimation of the actual copy number of the target chromosome because a significant number of nuclei will be truncated. This was elegantly shown by Hopman et al., who found that the number of signals per nucleus increased with section thickness.12 Interphase cytogenetics on tissue sections at best gives an impression of the highest copy number that can be present in a certain subpopulation.

For an accurate assessment of the copy number of a chromosome, intact nuclei can be isolated from 50 μm paraffin wax sections and used for interphase cytogenetics. Parallel sections of 5 μm can be used for histopathological identification of the specific tumour tissue areas, which can then be removed with a
For optimal in situ hybridisation results. An optional pretreatment consisted of incubating the slides in distilled water, 1 M NaSCN, 1 M LiCl, or 4 M guanidinium chloride in a shaking waterbath at 80°C for 10 minutes. The slides were then digested with 0-5% pepsin in either 0.01 M or 0.2 M HCl at 37°C. The length of the pepsin treatment varied from 15 to 60 minutes. Optional steps after the pepsin digestion were postfixation with 1% formaldehyde or 4% paraformaldehyde, and incubation with 1% hydroxylammoniumchloride. The slides were rinsed with PBS and dehydrated. Then 5 μl of hybridisation mixture was added under a coverslip of 18 × 18 mm². The probe and the target DNA were denatured simultaneously for 10 minutes at 80°C. In situ hybridisation was allowed to take place overnight at 37°C in a moist chamber with 60% formamide and 2 × SSC.

**IMMUNOCYTOCHEMICAL DETECTION**

After in situ hybridisation the slides were washed three times for five minutes each in 60% formamide/2 × SSC (pH 7.0) at room temperature. They were rinsed in 4 × SSC/0.05% Tween-20 and preincubated with 4 × SSC/5% non-fat dry milk. Immunological detection consisted of three consecutive incubations of 30 minutes at 37°C: avidin-D (1 in 100), biotinylated polyclonal goat-anti-avidin (1 in 100), and avidin-peroxidase (1 in 100) in 4 × SSC/5% non-fat dry milk. After washing in 4 × SSC/0.05% Tween-20, PBS, and 50 mM TRIS-HCl (pH 7.4) the slides were incubated in the dark for 10 minutes at room temperature with a solution of 0.05% dianisobenzidine, 0.05% H₂O₂, 1 mM imidazole in 50 mM TRIS-HCl (pH 7.4). The slides were counterstained with Mayer’s haematoxylin, dehydrated, and embedded with Fluoromount (BDH, England).

**RESULTS**

**ISOLATION OF NUCLEI**

The isolation of nuclei following the Hedley procedure resulted in different yields of individual nuclei for the different tissues. This was probably caused by differences in cellularity of the sections, the number of 50 μm sections of the various tissues used for isolation was adjusted. The percentage of nuclei which attached to the glass slide after the bucketchrifuge spin depended on the coating of the slides and the fluid in which the nuclei were centrifuged. Optimal combinations are: 70% acetic acid with ethanol/ether cleaned slides and 70% ethanol with poly-L-lysine coated slides. The loss of normal nuclei from the glass slides during the in situ hybridisation procedure was the same for each of these combinations and amounted to about 30% of the original number deposited. Because of its ease the first combination was used in further experiments. A remarkable difference between normal and tumour tissues was the fact that tumour nuclei which were isolated with 0.5% pepsin in 0.2 M HCl detached from the slides during the hybridisation procedure, while
tumour nuclei isolated in 0-01 M HCl and normal nuclei isolated with either procedure did not. Therefore, the isolations were performed for all tissues in 0-01 M HCl.

EFFECTS OF DIFFERENT PRETREATMENTS
To find an optimal balance between in situ hybridisation signals and morphology, variations were performed in the treatments of the sections and the isolated nuclei on the slides beforehand. Longer pepsin treatments provided, in general, better accessibility of the chromosomal DNA in the nuclei for the probes, but poorer morphology. The pepsin digesting conditions like time and pH (0-01 M or 0-2 M HCl) were varied for the different tissues and the best ones are summarised in tables 1-4. The pepsin pretreatment on nucleus preparations was milder than the one for tissue sections, as a logical consequence of the fact that the nuclei had already been in contact with pepsin during isolation. RNase treatment before the addition of pepsin did not improve the in situ hybridisation results.

According to Hopman et al., heating the slides in an 80°C waterbath in 1 M NaSCN or in distilled water before pepsin digestion gave better results on thin paraffin sections. NaSCN would, as a chaotropic agent, loosen bonds between nucleic acids and proteins, making the very compact chromatin proteins more accessible for pepsin. In our hands, sections of testis, brain, and lung displayed a dramatic loss in morphological detail and no increase in signal strength when the NaSCN pretreatment step was included. In contrast, sections of colon, kidney, and breast did show much stronger signals and only a slight loss of morphology. For these tissues we compared the effect of 10 minutes at 80°C in chaotropic agents such as 1 M NaSCN, 1 M LiCl, or 4 M guanidium chloride with distilled water. NaSCN and LiCl gave only slightly better results than guanidium chloride and water. This suggests that the beneficial effect is primarily due to the heating of the sections. Postfixation after the pepsin treatment with 1% formaldehyde or with 4% paraformaldehyde did not improve the in situ hybridisation results. Incubation with 1% hydroxylammoniumchloride to block residual aldehyde groups resulted in somewhat better in situ hybridisation results.

IN SITU HYBRIDISATION ON TISSUE SECTIONS
Table 1 summarises optimal conditions, morphology assessment, hybridisation signal intensity, and evaluability of the hybridisation signals for chromosome 1 and 17 specific probes on 5 μm sections of the various normal tissues investigated. Table 2 summarises the same for hybridisations on tissue sections of tumours. In general, the hybridisation with both probes resulted in distinct signals in a large proportion of nuclei. The necessary pretreatment steps often resulted in poor morphology: loss of intercellular structure, diminished nuclear counterstaining, and so on. As a consequence, for some types of tissue, it was practically impossible to evaluate to which nucleus the signals belonged. The same problem arose when there were many contiguous and overlapping nuclei, such as in lung tumour tissue (fig 1).

IN SITU HYBRIDISATION ON ISOLATED NUCLEI
The results on nuclei isolated from normal tissues seemed rather promising (table 3): all tissues gave good signals for both probes used. Tumour nuclei, however, gave less satisfactory results (table 4): only testis and brain gave clear signals that could be evaluated.

Figure 1 Photomicrograph of a 5 μm tissue section of an adenocarcinoma of the lung hybridised with the probe for the chromosomes 1 centromeres. Note that, due to contiguous and overlapping nuclei, it is not really possible to evaluate which hybridisation signals belong to which nucleus (Mayer's haematoxylin counterstain).
distributions are summarised in table 5. About 75% of the nuclei of normal tissues displayed two signals. This agrees with the findings of previous studies on normal lymphocytes and fibroblasts. The relatively high percentage of nuclei of normal breast tissue without any signal for chromosome 17 centromere (15%) probably reflects suboptimal hybridisation. Almost 30% of normal brain nuclei displayed only one large spot after hybridisation with the 17 centromeric probe. The same observation was recently made in nuclei isolated from fresh brain tissue samples, and was explained by somatic pairing of the two centromeres. The hybridisation on the testis tumour nuclei showed four signals in most of the nuclei for both chromosome 1 and 17 (table 5), reflecting tetraploidy.

Discussion
Over the past five years in situ hybridisation has been used increasingly more often in cytogenetic studies. One of the main advantages is its applicability to cells in interphase (“interphase cytogenetics”), thereby omitting cumbersome culture procedures. In this study we investigated whether interphase cytogenetics can be applied routinely to tissue that has been fixed in formalin and embedded in paraffin wax as it would permit retrospective analysis of tumours for chromosomal abnormalities. In situ hybridisation experiments were performed both on nuclei isolated from thick sections and on intact thin sections. For an exact assessment of the copy number of chromosomes in tumour cells hybridisations to isolated nuclei are to be preferred. Tissue sections, on the other hand, can provide information on the cell type showing the chromosomal aberration. A disadvantage of using tissue sections, clearly illustrated in our study, is the difficulty of identifying the individual nuclei with their corresponding signals in tissues with a high cellularity. In general, our results seem to favour the use of isolated nuclei (tables 1–4).

Two hundred nuclei were evaluated microscopically in isolated nuclei preparations of each tissue after in situ hybridisation with probes specific for the centromeric regions of chromosomes 1 or 17.
ology laboratories to invest more effort in reserving at least part of the freshly obtained tumour material for interphase cytogenetics, instead of fixing the complete sample in formalin.

In conclusion, our results show that although interphase cytogenetics on archival paraffin wax embedded tissue is feasible, fresh tumour material is clearly still the first choice for the study of numerical chromosome aberrations in solid tumours. Establishment of routinely applicable in situ hybridisation protocols for interphase cytogenetics on paraffin wax embedded tissue requires further research.
