Use of rapid carbohydrate utilisation test for identifying “Streptococcus milleri group”

J M Whitworth, P W Ross, I R Poxton

Abstract
A short series of biochemical and serological tests were developed for the rapid presumptive identification of “Streptococcus milleri group” isolates. One hundred and seventy seven streptococcal isolates were recovered from the mouths of 10 out of 12 healthy adult volunteers by use of a simple sampling procedure and a single selective medium. In all, 127 oral “S milleri group” isolates were identified by biochemical and serological tests, confirming the indigenous nature of these streptococci in the mouth. Most (70-1%) of “S milleri group” isolates were non-haemolytic, 26% were α-haemolytic, and 3-9% β-haemolytic. Fifty four (42.5%) were serologically typable, of which 46 were Lancefield group F, suggesting that the mouth is an important source of Lancefield group F streptococci. A collection of group F streptococci from a range of sources was indistinguishable from a collection of oral “S milleri group” isolates on the basis of the tests used, supporting the general synonymity of group F streptococci with the broader “S milleri group”.

The battery of tests was cheap and simple to perform, and was capable of identifying “S milleri group” isolates from a range of sources, including variants with wide sugar fermentation patterns.

The viridans streptococci have long been regarded as low grade pathogens contributing to the complex resident flora of a number of mucosal sites. Streptococci belonging to the “milleri group” are currently classified with the viridans streptococci, and are known to contribute to the resident flora of the gastrointestinal tract,1 the urogenital system,2 the upper respiratory tract,3 and the mouth, where a particular association with sheltered sites on hard surfaces has been shown.4 They are, however, unusual among the viridans streptococci in their association with deep-seated sepsis in a range of sites, including surgical sepsis,5 hepatic abscesses,6 pleural empyema,7 intracranial sepsis8 and odontogenic abscesses.9 The mouth has often been regarded as the source of “Streptococcus milleri group” strains involved in abscess formation in many of these sites.

Despite its widespread use in the clinical setting, the title “S milleri” has no official status in streptococcal taxonomy10 and is a title used to describe a collection of strains which have variously been referred to as Streptococcus anginosus,11 minute colony forming β haemolytic streptococci,12 Streptococcus MG,13 Streptococcus milleri,14 Streptococcus intermedius,15-17 Streptococcus constellatus,18 Streptococcus anginosus-constellatus,19 and Streptococcus MG-intermedius.20 The “S milleri group”, therefore, represents a complex aggregate of organisms which may display α, β, or non-haemolysis on blood agar culture media, and may variably possess Lancefield group antigens A, C, G, or F. Heterogeneity in traditional biochemical tests has also been observed.21 Recognised differences notwithstanding, these strains are currently classified within a single species, under the approved name S anginosus.21 Taxonomic uncertainty persists, however, and recent studies have shown three distinct genotypes within the “S milleri group”22; one homology group including the type strain of S constellatus, one including the type strain of S intermedius, and the final group including the type strain S anginosus. A very recent report from the same authors has also described a biochemical scheme for the reliable phenotypic differentiation of these three genotypes, suggesting that they are incorrectly classified within a single species.23

The aims of the current study were: (i) to design a simple and reliable protocol for the recovery of “S milleri group” isolates from defined sites in the oral cavity; (ii) to develop a simple, rapid, and cheap battery of biochemical and serological tests for the presumptive identification of “S milleri group” isolates from the mouth and other sources that would be capable of recognising the various haemolytic types, serological groups, and biotypes known to exist within this taxon; and (iii) to establish a culture collection of group F streptococcal strains from a range of sites, and of different haemolytic and biotypes.

Methods
Dental plaque was recovered on sterile McCall’s curettes from two non-inflamed sites in the mouths of 12 healthy adult volunteers (five men, seven women), lingual to a lower first permanent molar tooth and distolabial to an upper canine tooth. The plaque was dispersed into 1.0 ml reduced transport fluid (RTF).24 Samples were transported to the laboratory within one hour and dispersed in RTF by vortexing before serial dilution in RTF. Dilu-

BIOCHEMICAL IDENTIFICATION

Carbohydrate fermentation tests

Fermentation of mannitol, raffinose, sorbitol, melibiose and trehalose was by a method modified from the rapid carbohydrate utilisation test (RCUT) of Young.29 The RCUT was conveniently performed in the wells of microtitre plates as follows:

1. 100 μl of buffered salt solution containing neutral red indicator (BSS)28 were added to six wells in a microtitre plate, and 250 μl to a small, sterile glass tube for each organism to be examined. Control wells were also set up as indicated in the figure.

2. 25 μl of 10% (w/v) aqueous solutions of mannitol, raffinose, sorbitol, melibiose and trehalose were added, respectively, to one of five wells for each test organism, and to appropriate control wells as indicated in the figure.

3. Growth from a fresh, overnight blood-agar culture was harvested with a cotton-tipped swab, and used to make a dense suspension in the 250 μl BSS contained in the test tube. Volumes (25 μl) of this suspension were added to test wells of the microtitre plate, and to appropriate control wells (figure).

4. Plates were incubated at 37°C by floating in a waterbath, and a definitive reading (colour change of red to yellow) was made after four hours.

Voges-Proskauer (VP) reaction

This was achieved by the rapid method of Bucher and von Graevenitz,29 using fresh culture of Lancefield group F streptococcus (NCTC 10707) as a positive control.

Arginine hydrolysis

This was carried out according to the method of Niven et al.28 as described by Cowan and Steel,29 with a stock strain of Enterococcus faecalis as a positive control.

Aesculin hydrolysis

This was carried out using two methods: (i) the method of Cowan and Steel29; and (ii) the method of Brown et al.30 A stock strain of E. faecalis was the positive control in each test.

SEROLOGICAL IDENTIFICATION

Sero logical identification was performed by gel-diffusion in Ouchterlony gels.31

Antigenic extracts

C antigen was extracted from the cells contained in a heavy sweep from a fresh blood-agar culture by the method of El Kholy et al.32 Each day fresh cultures of laboratory stock strains of Lancefield group A, C, and G streptococci, and Lancefield group F streptococci (NCTC 10707) were used as controls.

Antiserum

Antiserum was raised in a Dutch rabbit by the method of Poxton.34 The vaccine was 10⁹ bacteria which had been irradiated with a lethal dose of ultraviolet light. Antiserum was raised

against Lancefield group F streptococcus (NCTC 10707). Commercial antisera (groups A, C, G, and F) were obtained from Wellcome.

Results
A collection of reference strains was first examined by the short series of biochemical tests to establish its ability to differentiate "S milleri group" strains from single strains of S sanguis (NCTC 7864), S salivarius (NCTC 8606), S mutans (NCTC 10449), and S mitior (NCTC 10712), and to establish the reproducibility of results. Table 2 shows the results of tests, which were repeated on three consecutive days and gave entirely reproducible results. RCUT tests were clearly read after four hours, and Voges-Proskauer tests after five hours. Determination of arginine hydrolysis required incubation for 24 hours, while ascorbic acid hydrolysis often required incubation for 48 hours before a definitive reading could be made.

The eight "S milleri group" reference strains tested represented a relatively homogeneous collection of strains, fermenting only trehalose, giving a positive Voges-Proskauer reaction, hydrolysing arginine, and in all but two cases hydrolysing aesculin.

Although differentiating "S milleri group" strains from the single representatives of S sanguis, S salivarius, S mutans, and S mitior, differentiation among the other strains was not entirely clear. The single S mutans strain, however, was clearly identified by its wide carbohydrate utilisation pattern, positive Voges-Proskauer reaction, aesculin hydrolysis, and its failure to hydrolyse arginine.

Serological tests correctly identified Lancefield group F streptococci (NCTC 10707, NCTC 5389, NCTC 10714), and S anginosus (NCTC 8037) as group F strains. None of the other strains reacted with the range of antisera used in this study. Serological results were clearly read within five hours.

A simple sampling procedure, in combination with a single selective medium, permitted the isolation of 177 streptococcal isolates which were examined further. Within this collection of isolates 127 "S milleri group" isolates were identified by the short series of tests from the mouths of 10 of the 12 subjects sampled.

The results of biochemical and serological tests for 127 "S milleri group" isolates, repeated in duplicate, are shown in table 3. Most isolates fermented trehalose, hydrolysed arginine and aesculin, and gave a positive Voges-Proskauer reaction. A few, however, utilised mannotol, raffinose, sorbitol or melibiose. Most (70-1%) isolates were non-haemolytic, and of the five (3-9%) β-haemolytic isolates, three were Lancefield group G and two were ungroupable within the range of antisera used. In total, 54 (42-5%) of the 127 oral "S milleri group" isolates were serologically groupable, most (n = 46) of these strains belonging to Lancefield group F. In all instances the results obtained with antisera raised against Lancefield group F streptococcus (NCTC 10707) agreed with the commercial group F antisemur. In addition to the 46 oral group F strains obtained in the current study, nine clinical group F strains and four NCTC reference strains (table 1) contributed to a collection of 59 Lancefield group F streptococcal strains. The range of biochemical profiles

encountered in this culture collection is shown in table 4. Thirty eight (64.4%) were non-
haemolytic, 16 (27.1%) α-haemolytic, and five (8.5%) β-haemolytic. Most (74.6%) formed a
biochemically homogeneous group, but strains were found which displayed differing fermentation
profiles. No differentiation could be made between Lancefield group F and non-Lancefield
group F "S. milleri" isolates on the basis of the biochemical tests used in this study.

Discussion
In the first part of this study a series of simple biochemical and serological tests were
developed for the presumptive identification of "S. milleri group" reference strains. Differentiation
of "milleri group" streptococci from a small collection of oral streptococcal reference
strains was readily achieved, though differentiation among other species tested was not always
clear. Although beyond the scope of the current study, it is suggested that a fuller evaluation
of this system with a broad range of oral streptococci of known identity would be required to
modify the range of tests for the presumptive identification of a greater number of species.

Tests for the production of hyaluronidase, and the ability to degrade synthetic fluorogenic
substrates described recently by Whiteley et al.,
were not included in this study, and the
differentiation of strains within the "S milleri
group" corresponding to S. anginosus, S. inter-
medius, and S. constellatus was consequently not
possible.

The single selective medium used in this
study proved effective for the recovery of "S
milleri group" isolates from the mouth and
confirmed the association of this group with the
human gingival crevice.

Oral "S. milleri group" isolates represented a
relatively homogeneous group on the basis of the
tests undertaken, though a small number of
isolates (9.4%) was encountered which were able
to ferment mannitol, raffinose, sorbitol, or
melibiose. This proportion of oral "S. milleri
group" isolates with wide sugar fermentation
profiles was comparable with the findings of Ball
and Parker.

In common with previous studies on "S
milleri group" isolates from the mouth, most
isolates found in our study were non-
haemolytic and possessed no recognisable
Lancefield grouping antigen, properties typical of the S. intermedius taxon described by Whiteley
et al. A high proportion of oral "S. milleri"
group" isolates, however, were serologically
groupable, and of these, Lancefield group F was
by far the commonest, which agrees with the
findings of other workers. All of the oral
group F isolates found were either α or non-
haemolytic, suggesting that they would most
likely belong to the S. anginosus taxon.

Further tests would be required to confirm
these intuitive associations because it is recog-
ised that haemolytic reactions, Lancefield
group status, and behaviour in traditional bio-
chemical tests are of little practical value in
identifying the three taxa shown within the "S
milleri group". The results of this study supported this observation because a collection
of Lancefield group F streptococci from a range
of sources was indistinguishable from a collec-
tion of oral "S. milleri group" isolates on the
basis of the tests used.

These observations notwithstanding, the
system of tests described in the current report
were regarded as satisfactory for the rapid
presumptive identification of "S. milleri group"
isolates from a range of sources. Inoculation
tests from a pure plate culture, in addition to
short incubation times in non-nutrient
medium, reduced to a minimum the potential
problems of contamination, while the small
volumes of reagents and the use of non-sterile
microtitre plates kept the cost of media and
consumables low.
