Undifferentiated carcinoma of parotid gland

J I López, J Alfaro, C Ballestin

Abstract
Two cases of undifferentiated carcinomas of the major salivary glands were studied using immunohistochemical techniques. Results showed that this entity was a high grade malignant neoplasm arising from the excretory duct. Despite the undifferentiated appearance multiple immunophenotypes were evident in both cases.

Well defined, undifferentiated carcinomas of salivary glands are fairly uncommon high grade neoplasms. These tumours arise in major salivary glands, mainly in the parotid. Despite the fact that the light microscopic features are undifferentiated, electron microscopic studies have shown glandular or neuroendocrine features in some of them.

In an attempt to detect differentiating features we recently studied two cases using immunohistochemistry.

Case reports
CASE 1
A 54 year old man presented with a tumour mass on the left side of his neck. The lesion had grown quickly over two months. Ipsilateral subdigastric lymph node metastases were also detected on physical examination. Lumpectomy and lymphadenectomy were performed. Macroscopically, the tumour measured 6 cm and showed multiple haemorrhagic foci. He died of metastatic disease three months later.

CASE 2
A 60 year old man presented with a large, left sided tumour mass on his neck. The tumour measured 12 cm. Bilateral lymph node metastases on the lower neck were detected. Palliative surgical resection was performed. Macroscopically, there were multiple haemorrhagic foci with necrotic areas. Death followed rapidly. A post mortem examination was not performed.

In both cases metastatic disease from skin, lung, and gastrointestinal tract was ruled out as far as possible.

Both tumours were located in the parotid gland, and morphologically, fulfilled the light microscopic criteria of undifferentiated carcinomas of major salivary gland. Small or inter-
Immuno-histochemical panel and results

AEI (acidic keratins). CAM 5-2 (keratins 8, 18, 19), keratin 903 (keratins 1, 5, 10, 11), keratin 904 (keratin 1), EMA (epithelial membrane antigen), CEA (carcinoembryonic antigen), enolase (neurone specific gamma-enolase), actin (muscle specific actin).

mediate hyperchromatic cells with a high nuclear:cytoplasmic ratio and frequent mitoses were arranged in large lobes and strands. No evidence of differentiation was observed. Necrosis and bleeding were prominent features. An immunohistochemical study using several epithelial, mesenchymal, and neuroendocrine markers was performed (table).

Discussion

The immunohistochemical results expressed in the table basically agree with those of Hui et al.2 Because of negative actin and S-100 protein immunostaining, an absence of myoepithelial cells could be assumed in our cases. Differentiation towards both glandular and neuroendocrine features occurred in case 1, as was shown by positivity for AEI, CAM 5-2, CEA, and gamma-enolase. A complex expression of cytokeratins was evident in case 2; both glandular and non-keratinising squamous differentiation were seen.

The absence of a myoepithelial component in these cases has not been reported previously. According to Batsakis et al.,3 this suggests a presumptive histogenetic origin from the excretory duct. On the other hand, multidirectional differentiation pathways occurring during oncogenesis may permit the simultaneous development of neuroendocrine and exocrine components. This fact, observed in case 1, has also been recently reported in undifferentiated carcinoma of parotid glanda as well as in other salivary gland neoplasms.b,c

Finally, expression of keratin 903 (cyto-keratins 1, 5, 10, and 11, expressed by basal cells), as well as CAM 5-2 keratin (cyto-keratins 8, 18, and 19) reflects the fact that multiple immunophenotypes occur in these carcinomas and adds further support to the notion of occult differentiating pathways.

Morbidity survey of post mortem room staff

A J Hall, T C Aw, J M Harrington

Abstract

A retrospective study of post mortem staff who had taken leave due to sickness was carried out over a 12 month period throughout England and Wales. Eight hundred and nineteen post mortem room personnel (representing a 57% response) replied to individual postal questionnaires regarding their sick leave of two days or more, for the period June 1985 to June 1986. Complete responses were available for 751. Post mortem room technical staff reported more mean days sickness per person (7·8) than either pathologists (1·6) or a control group of coroners' officers (3·9). The annual incidence rate (frequency by spells) was also higher among technicians than the other two groups. Technical staff had more infectious disease (0·7-3 mean days of absense compared with pathologists (0·10) or coroners' officers (0·12)) and more frequent absences due to cuts and lacerations.

Infection risks associated with health care work were at one time considered unavoidable. Despite epidemiological evidence that a demonstrable risk to health exists3,4 and the introduction of corresponding health and safety legislation, occupational morbidity in particular subgroups of health care workers is still evident.4,5 Certain categories of health care work are perceived to carry a greater inherent health risk, not only from contact with diseased subjects and blood and body fluids, but also from injury through the use of potentially dangerous equipment. One such occupation is post mortem work where both technical and medical staff are at risk.
