spondylitis. 5 Hajjaj-Hassiouni et al described two cases of ankylosing spondylitis with the nephrotic syndrome where amyloid was demonstrated in a rectal biopsy specimen, 6 Gefriaud et al followed up six patients with systemic AA amyloidosis and ankylosing spondylitis. 7 Renal failure eventually occurred in all six between three and 31 years (with a mean of 19 years) after the onset of rheumatological symptoms.

Amyloidosis is a well recognised cause of the nephrotic syndrome, and end stage renal failure is the cause of death in 13–68% of cases of systemic AA amyloidosis. 5 7–10 AA amyloidosis may present many years after the onset of the underlying inflammatory disorder, which may appear to be clinically inactive at the time of presentation. 7 In a recently published series from the Mayo Clinic the mean time elapsed between onset of symptoms attributable to inflammatory disease and a tissue diagnosis of AA amyloid was 18.3 years. 7

Our patient developed a nephrotic syndrome 44 years after the onset of symptoms attributable to ankylosing spondylitis. At the time of writing he retains adequate renal function. Progression of his renal disease has thus been slower than in the six patients in Gefriaud’s series. 6

Immunostaining of amyloid with specific antisera to the components of amyloid fibrils is not routinely performed in many pathology departments including, until now, our own. In the authors’ opinion this case shows that immunostaining of amyloid should be routinely adopted to avoid overlooking occult or apparently quiescent underlying disease.

We thank Professor Robert A Kyle for reading the manuscript and giving us the benefit of his long experience in the field of amyloidosis.

Lobular carcinoma in a mammary hamartoma

Abstract

Mammary hamatomas are uncommon breast lesions, sometimes presenting as mammographic abnormalities which require pathological clarification. Previous cases have all been benign. A unique case of mammary hamartoma containing atypical lobular hyperplasia (ALH), lobular carcinoma in situ (LCIS), and foci of microinvasive lobular carcinoma is presented. The need for adequately sampling macroscopically innocuous breast lesions is emphasised.

(J Clin Pathol 1992;45:936–937)

Case report

A 59 year old woman had a 5 cm, well defined opacity incorporating a fatty component, which was located in the upper inner quadrant of the left breast, detected at mammography (fig 1). A soft, round, mobile mass was palpable and this was considered to be benign clinically. A fine needle aspirate showed very few, small clusters of benign epithelial cells. Because of the patient’s anxiety, an excision biopsy was performed.

Pathology

The specimen measured 6 × 5 × 3 cm and contained an oval well circumscribed mass measuring 3 cm in maximum diameter. It had a yellow and white variegated cut surface and was firm and rubbery in consistency. Macroscopically, the lesion was focally surrounded by a thin layer of fibrous tissue containing occasional compressed ducts. The overall pattern consisted of individual and clustered lobular units separated by dense, hyalinised fibrous tissue which were separated by abundant fatty

Discussion

Arrigoni described the characteristic macroscopic and microscopic features of a breast lesion which he termed mammary hamartoma. These lesions are well circumscribed and both clinically and radiologically may resemble a fibroadenoma. Histologically, they are composed of acinar units, arranged in a lobular pattern within a hyalinised, fibrous stroma and containing variable amounts of fat in the interlobular regions. In addition to these typical features, this case also contained foci of ALH and LCIS with two foci of microinvasive lobular carcinoma. Although epithelial hyperplasia is reported as occurring only rarely, neoplastic lesions have not been documented in mammmary hamartomas before as far as we know. It seems likely that its occurrence in this case, as in fibroadenomas, is coincidental and certainly not unexpected. Nevertheless, it emphasises the need for adequate sampling of macroscopically innocuous lesions as just over half the sections (57%) contained lobular neoplasia and only two (14%) contained microinvasive carcinoma.

We thank Miss M Garner for excellent secretarial assistance and Miss P Rowland for the photomicrographs.

hyperplasia was present in the small amount of attached fatty breast tissue.
